Introduction

'A Byte of Python' is a book on programming using the Python language. It serves as a tutorial or guide to the Python language for a beginner audience. If all you know about computers is how to save text files, then this is the book for you.

This book is updated for the new Python 3.0 language. If you are looking for a tutorial on the current Python 2.x version, please download the previous revision of the book ^[5]. On the same note, if you're wondering whether to learn Python 2.x or 3.x, then read this article by James Bennett ^[6].

Here are what people are saying about the book:

Feedback From Readers

This is the best beginner's tutorial I've ever seen! Thank you for your effort.

- *Walt Michalik* (wmich50-at-theramp-dot-net)

You've made the best Python tutorial I've found on the Net. Great work. Thanks!

- *Joshua Robin* (joshrob-at-poczta-dot-onet-dot-pl)

Hi, I'm from Dominican Republic. My name is Pavel, recently I read your book 'A Byte of Python' and I consider it excellent!! :). I learnt much from all the examples. Your book is of great help for newbies like me...

- *Pavel Simo* (pavel-dot-simo-at-gmail-dot-com)

I recently finished reading Byte of Python, and I thought I really ought to thank you. I was very sad to reach the final pages as I now have to go back to dull, tedious oreilly or etc. manuals for learning about python. Anyway, I really appreciate your book

- *Samuel Young* (sy-one-three-seven-at-gmail-dot-com)

Dear Swaroop, I am taking a class from an instructor that has no interest in teaching. We are using Learning Python, second edition, by O'Reilly. It is not a text for beginner without any programming knowledge, and an instructor that should be working in another field. Thank you very much for your book, without it I would be clueless about Python and programming. Thanks a million, you are able to 'break the message down' to a level that beginners can understand and not everyone can.

- *Joseph Duarte* (jduarte1-at-cfl-dot-rr-dot-com)

I love your book! It is the greatest Python tutorial ever, and a very useful reference. Brilliant, a true masterpiece! Keep up the good work!

- *Chris-André Sommerseth*

I'm just e-mailing you to thank you for writing Byte of Python online. I had been attempting Python for a few months prior to stumbling across your book, and although I made limited success with pyGame, I never completed a program.

Thanks to your simplification of the categories, Python actually seems a reachable goal. It seems like I have finally learned the foundations and I can continue into my real goal, game development.

...

Once again, thanks VERY much for placing such a structured and helpful guide to basic programming on the web. It shoved me into and out of OOP with an understanding where two text books had failed.

- *Matt Gallivan* (m-underscore-gallivan12-at-hotmail-dot-com)

I would like to thank you for your book 'A byte of python' which i myself find the best way to learn python. I am a 15 year old i live in egypt my name is Ahmed. Python was my second programming language i learn visual basic 6 at school but didn't enjoy it, however i really enjoyed learning python. I made the addressbook program and i was sucessful. i will try to start make more programs and read python programs (if you could tell me source that would be helpful). I will also start on learning java and if you can tell me where to find a tutorial as good as yours for java that would help me a lot. Thanx.

- *Ahmed Mohammed* (sedo-underscore-91-at-hotmail-dot-com)

A wonderful resource for beginners wanting to learn more about Python is the 110-page PDF tutorial A Byte of Python by Swaroop C H. It is well-written, easy to follow, and may be the best introduction to Python programming available.

- *Drew Ames* in an article on Scripting Scribus ^[7] published on Linux.com

Yesterday I got through most of Byte of Python on my Nokia N800 and it's the easiest and most concise introduction to Python I have yet encountered. Highly recommended as a starting point for learning Python.

- *Jason Delpont* on his weblog ^[8]

Academic Courses

This book is being used as instructional material in various educational institutions:

1. 'Principles of Programming Languages' course at Vrije Universiteit, Amsterdam ^[9]
 2. 'Basic Concepts of Computing' course at University of California, Davis ^[10]
 3. 'Programming With Python' course at Harvard University ^[11]
 4. 'Introduction to Programming' course at University of Leeds ^[12]
 5. 'Introduction to Application Programming' course at Boston University ^[13]
 6. 'Information Technology Skills for Meteorology' course at University of Oklahoma ^[14]
 7. 'Geoprocessing' course at Michigan State University ^[15]
 8. 'Multi Agent Semantic Web Systems' course at the University of Edinburgh ^[16]

Python en:Translations

There are many translations of the book available in different human languages, thanks to many tireless volunteers!

If you want to help these translations, please see the list of volunteers and languages below and decide if you want to start a new translation or help in existing translation projects.

If you plan to start a new translation, please read the Translation Howto.

Chinese

Juan Shen (orion-underscore-val-at-163-dot-com) has volunteered to translate the book to Chinese.

what - I am a postgraduate at Wireless Telecommunication Graduate School, Beijing University of Technology, China PR. My current research interest is on the synchronization, channel estimation and multi-user detection of multicarrier CDMA system. Python is my major programming language for daily simulation and research job, with the help of Python Numeric, actually. I learned Python just half a year before, but as you can see, it's really easy-understanding, easy-to-use and productive. Just as what is ensured in Swaroop's book, 'It's my favorite programming language now'. 'A Byte of Python' is my tutorial to learn Python. It's clear and effective to lead you into a world of Python in the shortest time. It's not too long, but efficiently covers almost all important things in Python. I think 'A Byte of Python' should be strongly recommendable for newbies as their first Python tutorial. Just dedicate my translation to the potential millions of Python users in China.

Chinese Traditional

Fred Lin (gasolin-at-gmail-dot-com) has volunteered to translate the book to Chinese Traditional.

It is available at <http://code.google.com/p/zhpy/wiki/ByteOfZhpy> (<http://code.google.com/p/zhpy/wiki/ByteOfZhpy>).

An exciting feature of this translation is that it also contains the *executable chinese python sources* side by side with the original python sources.

Fred Lin - I'm working as a network firmware engineer at Delta Network, and I'm also a contributor of TurboGears web framework. As a python evangelist (:-p), I need some material to promote python language. I found 'A Byte of Python' hit the sweet point for both newbies and experienced programmers. 'A Byte of Python' elaborates the python essentials with affordable size. The translation are originally based on simplified chinese version, and soon a lot of rewrite were made to fit the current wiki version and the quality of reading. The recent chinese traditional version also featured with executable chinese python sources, which are achieved by my new 'zhpy' (python in chinese) project (launch from Aug 07). zhpy(pronounce (Z.H.?, or zippy) build a layer upon python to translate or interact with python in chinese(Traditional or Simplified). This project is mainly aimed for education.

Italian

Enrico Morelli (mr-dot-mlucci-at-gmail-dot-com) and Massimo Lucci (morelli-at-cerm-dot-unifi-dot-it) have volunteered to translate the book to Italian.

The Italian translation is present at www.gentoo.it/Programmazione/byteofpython (<http://www.gentoo.it/Programmazione/byteofpython>). The new translation is in progress and start with "Prefazione".

Massimo Lucci and Enrico Morelli - we are working at the University of Florence (Italy) - Chemistry Department. I (Massimo) as service engineer and system administrator for Nuclear Magnetic Resonance Spectrometers; Enrico as service engineer and system administrator for our CED and parallel / clustered systems. We are programming on python since about seven years, we had experience working with Linux platforms since ten years. In Italy we are responsible and administrator for www.gentoo.it web site for Gentoo/Linux distribution and www.nmr.it (now under construction) for Nuclear Magnetic Resonance applications and Congress Organization and Managements. That's all! We are impressed by the smart language used on your Book and we think this is essential for approaching the Python to new users (we are thinking about hundred of students and researcher working on our labs).

German

Lutz Horn (lutz-dot-horn-at-gmx-dot-de), Bernd Hengelein (bernd-dot-hengelein-at-gmail-dot-com) and Christoph Zwerschke (cito-at-online-dot-de) have volunteered to translate the book to German.

Their translation is located at <http://abop-german.berlios.de> (<http://abop-german.berlios.de>).

Lutz Horn : I'm 32 years old and have a degree of Mathematics from University of Heidelberg, Germany. Currently I'm working as a software engineer on a publicly funded project to build a web portal for all things related to computer science in Germany. The main language I use as a professional is Java, but I try to do as much as possible with Python behind the scenes. Especially text analysis and conversion is very easy with Python. I'm not very familiar with GUI toolkits, since most of my programming is about web applications, where the user interface is build using Java frameworks like Struts. Currently I try to make more use of the functional programming features of Python and of generators. After taking a short look into Ruby, I was very impressed with the use of blocks in this language. Generally I like the dynamic nature of languages like Python and Ruby since it allows me to do things not possible in more static languages like Java. I've searched for some kind of introduction to programming, suitable to teach a complete non-programmer. I've found the book 'How to Think Like a Computer Scientist: Learning with Python', and 'Dive into Python'. The first is good for beginners but too long to translate. The second is not suitable for beginners. I think 'A Byte of Python' falls nicely between these, since it is not too long, written to the point, and at the same time verbose enough to teach a newbie. Besides this, I like the simple DocBook structure, which makes translating the text a generation the output in various formats a charm.

Bernd Hengelein : Lutz and me are going to do the german translation together. We just started with the intro and preface but we will keep you informed about the progress we make. Ok, now some personal things about me. I am 34 years old and playing with computers since the 1980's, when the "Commodore C64" ruled the nurseries. After studying computer science I started working as a software engineer. Currently I am working in the field of medical imaging for a major german company. Although C++ is the main language I (have to) use for my daily work, I am constantly looking for new things to learn. Last year I fell in love with Python, which is a wonderful language, both for its possibilities and its beauty. I read somewhere in the net about a guy who said that he likes python, because the code looks so beautiful. In my opinion he's absolutly right. At the time I decided to learn python, I noticed that there is very little good documentation in german available. When I came across your book the spontaneous idea of a german translation crossed my mind. Luckily, Lutz had the same idea and we can now divide the work. I am looking forward to a good cooperation!

Norwegian (bokmål)

Eirik Vågeskar (or Vages) is a high school student at Sandvika videregående skole (http://no.wikipedia.org/wiki/Sandvika_videregående_skole) in Norway, a blogger (<http://forbedre.blogspot.com/>) and currently translating the book to Norwegian (bokmål). The translation is in progress, and you can check the table of contents for more details.

Eirik Vågeskar: I have always wanted to program, but because I speak a small language, the learning process was much harder. Most tutorials and books are written in very technical English, so most high school graduates will not even have the vocabulary to understand what the tutorial is about. When I discovered this book, all my problems were solved. "A Byte of Python" used simple non-technical language to explain a programming language that is just as simple, and these two things make learning Python fun. After reading half of the book, I decided that the book was worth translating. I hope the translation will help people who have found themselves in the same situation as me (especially young people), and maybe help spread interest for the language among people with less technical knowledge.

Indonesian

Daniel (daniel-dot-mirror-at-gmail-dot-com) is translating the book to Indonesian at <http://python.or.id/moin.cgi/ByteofPython>

Polish

Dominik Kozaczko (dkozaczko-at-gmail-dot-com) has volunteered to translate the book to Polish. Translation is in progress and it's main page is available here: Ukąś Pythona (http://wiki.mercury.lo5.bielsko.pl/index.php/Ukąś_Pythoną).

Dominik Kozaczko - I'm a Computer Science and Information Technology teacher.

Catalan

Moises Gomez (moisesgomezgiron-at-gmail-dot-com) has volunteered to translate the book to Catalan. The translation is in progress, and starts with the chapter "Taula de continguts".

Moisès Gómez - I am a developer and also a teacher of programming (normally for people without any previous experience). Some time ago I needed to learn how to program in Python, and Swaroop's work was really helpful. Clear, concise, and complete enough. Just what I needed. After this experience, I thought some other people in my country could take benefit from it too. But English language can be a barrier. So, why not try to translate it? And I did for a previous version of BoP. In my country there are two official languages. I selected the Catalan language assuming that others will translate it to the more widespread Spanish.

Portuguese

Fidel Viegas (fidel-dot-viegas-at-gmail-dot-com) has volunteered to translate the book to Portuguese.

Romanian

Paul-Sebastian Manole (brokenthorn-at-gmail-dot-com) has volunteered to translate this book to Romanian.

Paul-Sebastian Manole - I'm a second year Computer Science student at Spiru Haret University, here in Romania. I'm more of a self-taught programmer and decided to learn a new language, Python. The web told me there was no better way to do so but read *A Byte of Python*. That's how popular this book is (congratulations to the author for writing such an easy to read book). I started liking Python so I decided to help translate the latest version of Swaroop's book in Romanian. Although I could be the one with the first initiative, I'm just one volunteer so if you can help, please join me.

The translation is being done here (http://www.swaroopch.com/notes/Python_ro).

Brazilian Portuguese

Rodrigo Amaral (<http://rodrigoamaral.net>) (rodrigoamaral-at-gmail-dot-com) has volunteered to translate the book to Brazilian Portuguese...

French

Gregory (coulix-at-ozforces-dot-com-dot-au) has volunteered to translate the book to French.

Danish

Lars Petersen (lars-at-ioflux-dot-net) has volunteered to translate the book to Danish.

Spanish

Alfonso de la Guarda Reyes (alfonsodg-at-ictechperu-dot-net) and Gustavo Echeverria (gustavo-dot-echeverria-at-gmail-dot-com) have volunteered to translate the book to

Spanish. The translation is in progress, you can read the spanish (argentinian) translation starting by the table of contents (tabla de contenidos).

Gustavo Echeverria: I work as a software engineer in Argentina. I use mostly C# and .Net technologies at work but strictly Python or Ruby in my personal projects. I knew Python many years ago and I got stuck immediately. Not so long after knowing Python I discovered this book and it helped me to learn the language. Then I volunteered to translate the book to Spanish. Now, after receiving some requests, I've begun to translate "A Byte of Python" with the help of Maximiliano Soler.

Arabic

Alaa Abadi (alaanassir-at-gmail-dot-com) has volunteered to translate the book to Arabic. ISA .

Swedish

Mikael Jacobsson (leochingwake-at-gmail-dot-com) has volunteered to translate the book to Swedish.

Russian and Ukranian

Averkiev Andrey (averkiyev-at-ukr-dot-net) has volunteered to translate the book to Russian, and perhaps Ukranian (time permitting).

Turkish

Türker SEZER (tsezer-at-btturk-dot-net) and Bugra Cakir (bugracakir-at-gmail-dot-com) have volunteered to translate the book to Turkish.

Mongolian

Ariunsanaa Tunjin (tariunsanaa-at-yahoo-dot-com) has volunteered to translate the book to Mongolian.

Note

Replace '-at-' with '@' , '-dot-' with '.' and '-underscore-' with '_' in the email addresses mentioned on this page. Dashes in other places in the email address remain as-is.

Python en:Preface

Python is probably one of the few programming languages which is both simple and powerful. This is good for both and beginners as well as experts, and more importantly, is fun to program with. This book aims to help you learn this wonderful language and show how to get things done quickly and painlessly - in effect 'The Perfect Anti-venom to your programming problems'.

Who This Book Is For

This book serves as a guide or tutorial to the Python programming language. It is mainly targeted at newbies. It is useful for experienced programmers as well.

The aim is that if all you know about computers is how to save text files, then you can learn Python from this book. If you have previous programming experience, then you can also learn Python from this book.

If you do have previous programming experience, you will be interested in the differences between Python and your favorite programming language - I have highlighted many such differences. A little warning though, Python is soon going to become your favorite programming language!

History Lesson

I first started with Python when I needed to write an installer for a software I had written called 'Diamond' so that I could make the installation easy. I had to choose between Python and Perl bindings for the Qt library. I did some research on the web and I came across an article where Eric S. Raymond, the famous and respected hacker, talked about how Python has become his favorite programming language. I also found out that the PyQt bindings were more mature compared to Perl-Qt. So, I decided that Python was the language for me.

Then, I started searching for a good book on Python. I couldn't find any! I did find some O'Reilly books but they were either too expensive or were more like a reference manual than a guide. So, I settled for the documentation that came with Python. However, it was too brief and small. It did give a good idea about Python but was not complete. I managed with it since I had previous programming experience, but it was unsuitable for newbies.

About six months after my first brush with Python, I installed the (then) latest Red Hat 9.0 Linux and I was playing around with KWord. I got excited about it and suddenly got the idea of writing some stuff on Python. I started writing a few pages but it quickly became 30 pages long. Then, I became serious about making it more useful in a book form. After a *lot* of rewrites, it has reached a stage where it has become a useful guide to learning the Python language. I consider this book to be my contribution and tribute to the open source community.

This book started out as my personal notes on Python and I still consider it in the same way, although I've taken a lot of effort to make it more palatable to others :)

In the true spirit of open source, I have received lots of constructive suggestions, criticisms and feedback from enthusiastic readers which has helped me improve this book a lot.

Status Of The Book

Changes since the last major revision in March 2005 is updating for the Python 3.0 release (expected in August/September 2008). Since the Python 3.0 language itself is still not finalized/released, this book is constantly undergoing changes. However, in the spirit of the open source philosophy of "Release Early, Release Often", the updated book has been released and is constantly being updated.

The book needs the help of its readers such as yourselves to point out any parts of the book which are not good, not comprehensible or are simply wrong. Please write to the main author (<http://www.swaroopch.com/contact/>) or the respective translators with your comments and suggestions.

It's a constant tussle to balance this book between a beginner's needs and the tendency towards 'completeness' of information. It would be helpful if readers also gave feedback on how much depth this book should go into.

Something To Think About

There are two ways of constructing a software design: one way is to make it so simple that there are obviously no deficiencies; the other is to make it so complicated that there are no obvious deficiencies.

-- C. A. R. Hoare

Success in life is a matter not so much of talent and opportunity as of concentration and perseverance.

Python en:Introduction

Introduction

Python is one of those rare languages which can claim to be both **simple** and **powerful**. You will find that you will be pleasantly surprised on how easy it is to concentrate on the solution to the problem rather than the syntax and structure of the language you are programming in.

The official introduction to Python is:

Python is an easy to learn, powerful programming language. It has efficient high-level data structures and a simple but effective approach to object-oriented programming. Python's elegant syntax and dynamic typing, together with its interpreted nature, make it an ideal language for scripting and rapid application development in many areas on most platforms.

I will discuss most of these features in more detail in the next section.

Note

Guido van Rossum, the creator of the Python language, named the language after the BBC show "Monty Python's Flying Circus". He doesn't particularly like snakes that kill animals for food by winding their long bodies around them and crushing them.

Features of Python

Simple

Python is a simple and minimalistic language. Reading a good Python program feels almost like reading English, although very strict English! This pseudo-code nature of Python is one of its greatest strengths. It allows you to concentrate on the solution to the problem rather than the language itself.

Easy to Learn

As you will see, Python is extremely easy to get started with. Python has an extraordinarily simple syntax, as already mentioned.

Free and Open Source

Python is an example of a *FLOSS* (Free/Libre and Open Source Software). In simple terms, you can freely distribute copies of this software, read its source code, make changes to it, and use pieces of it in new free programs. FLOSS is based on the concept of a community which shares knowledge. This is one of the reasons why Python is so good - it has been created and is constantly improved by a community who just want to see a better Python.

High-level Language

When you write programs in Python, you never need to bother about the low-level details such as managing the memory used by your program, etc.

Portable

Due to its open-source nature, Python has been ported to (i.e. changed to make it work on) many platforms. All your Python programs can work on any of these platforms without requiring any changes at all if you are careful enough to avoid any

system-dependent features.

You can use Python on Linux, Windows, FreeBSD, Macintosh, Solaris, OS/2, Amiga, AROS, AS/400, BeOS, OS/390, z/OS, Palm OS, QNX, VMS, Psion, Acorn RISC OS, VxWorks, PlayStation, Sharp Zaurus, Windows CE and even PocketPC !

Interpreted

This requires a bit of explanation.

A program written in a compiled language like C or C++ is converted from the source language i.e. C or C++ into a language that is spoken by your computer (binary code i.e. 0s and 1s) using a compiler with various flags and options. When you run the program, the linker/loader software copies the program from hard disk to memory and starts running it.

Python, on the other hand, does not need compilation to binary. You just *run* the program directly from the source code. Internally, Python converts the source code into an intermediate form called bytecodes and then translates this into the native language of your computer and then runs it. All this, actually, makes using Python much easier since you don't have to worry about compiling the program, making sure that the proper libraries are linked and loaded, etc, etc. This also makes your Python programs much more portable, since you can just copy your Python program onto another computer and it just works!

Object Oriented

Python supports procedure-oriented programming as well as object-oriented programming. In *procedure-oriented* languages, the program is built around procedures or functions which are nothing but reusable pieces of programs. In *object-oriented* languages, the program is built around objects which combine data and functionality. Python has a very powerful but simplistic way of doing OOP, especially when compared to big languages like C++ or Java.

Extensible

If you need a critical piece of code to run very fast or want to have some piece of algorithm not to be open, you can code that part of your program in C or C++ and then use it from your Python program.

Embeddable

You can embed Python within your C/C++ programs to give 'scripting' capabilities for your program's users.

Extensive Libraries

The Python Standard Library is huge indeed. It can help you do various things involving regular expressions, documentation generation, unit testing, threading, databases, web browsers, CGI, FTP, email, XML, XML-RPC, HTML, WAV files, cryptography, GUI (graphical user interfaces), Tk, and other system-dependent stuff. Remember, all this is always available wherever Python is installed. This is called the 'Batteries Included' philosophy of Python.

Besides, the standard library, there are various other high-quality libraries such as wxPython (<http://www.wxpython.org>) , Twisted (<http://www.twistedmatrix.com/products/twisted>), Python Imaging Library (<http://www.pythonware.com/products/pil/index.htm>) and many more.

Python is indeed an exciting and powerful language. It has the right combination of performance and features that make writing programs in Python both fun and easy.

Why not Perl?

If you didn't know already, Perl is another extremely popular open source interpreted programming language.

If you have ever tried writing a large program in Perl, you would have answered this question yourself! In other words, Perl programs are easy when they are small and it excels at small hacks and scripts to 'get work done'. However, they quickly become unwieldy once you start writing bigger programs and I am speaking this out of my experience writing large Perl programs at Yahoo!

When compared to Perl, Python programs are definitely simpler, clearer, easier to write and hence more understandable and maintainable. I do admire Perl and I do use it on a daily basis for various things but whenever I write a program, I always start thinking in terms of Python because it has become so natural for me. Perl has undergone so many hacks and changes, that it feels like it is one big (but one hell of a) hack. Sadly, the upcoming Perl 6 does not seem to be making any improvements regarding this.

The only and very significant advantage that I feel Perl has, is its huge CPAN (<http://cpan.perl.org>) library - the Comprehensive Perl Archive Network. As the name suggests, this is a humongous collection of Perl modules and it is simply mind-boggling because of its sheer size and depth - you can do virtually anything you can do with a computer using these modules. One of the reasons that Perl has more libraries than Python is that it has been around for a much longer time than Python. However this seems to be changing with the growing Python Package Index (<http://pypi.python.org/pypi>).

Why not Ruby?

If you didn't know already, Ruby is another popular open source interpreted programming language.

If you already like and use Ruby, then I would definitely recommend you to continue using it.

For other people who have not used it and are trying to judge whether to learn Python or to learn Ruby, then I would recommend Python, purely from an ease-of-learning perspective. I personally found it hard to grok the Ruby language, but for people who understand Ruby, they all praise the beauty of the language. Unfortunately, I am not as lucky.

What Programmers Say

You may find it interesting to read what great hackers like ESR have to say about Python:

- **Eric S. Raymond** is the author of "The Cathedral and the Bazaar" and is also the person who coined the term *Open Source*. He says that Python has become his favorite programming language (<http://www.linuxjournal.com/article.php?sid=3882>). This article was the real inspiration for my first brush with Python.
 - **Bruce Eckel** is the author of the famous *Thinking in Java* and *Thinking in C++* books. He says that no language has made him more productive than Python. He says that Python is perhaps the only language that focuses on making things easier for the
-

programmer. Read the complete interview (<http://www.artima.com/intv/aboutme.html>) for more details.

- **Peter Norvig** is a well-known Lisp author and Director of Search Quality at Google (thanks to Guido van Rossum for pointing that out). He says that Python has always been an integral part of Google. You can actually verify this statement by looking at the Google Jobs (<http://www.google.com/jobs/index.html>) page which lists Python knowledge as a requirement for software engineers.

About Python 3.0

Python 3.0 is the new version of the language. It is sometimes referred to as Python 3000 or Py3K.

The main reason for a major new version of Python is to remove all the small problems and nitpicks that have accumulated over the years and to make the language even more clean.

If you already have a lot of Python 2.x code, then there is a utility to assist you to convert 2.x to 3.x source (<http://docs.python.org/dev/3.0/library/2to3.html>).

More details are at:

- Guido van Rossum's introduction (<http://www.artima.com/weblogs/viewpost.jsp?thread=208549>)
- What's New in Python 2.6 (<http://docs.python.org/dev/whatsnew/2.6.html>) (features significantly different from previous Python 2.x versions and most likely will be included in Python 3.0)
- What's New in Python 3.0 (<http://docs.python.org/dev/3.0/whatsnew/3.0.html>)
- Python 2.6 and 3.0 Release Schedule (<http://www.python.org/dev/peps/pep-0361/>)
- Python 3000 (the official authoritative list of proposed changes) (<http://www.python.org/dev/peps/pep-3000/>)
- Miscellaneous Python 3.0 Plans (<http://www.python.org/dev/peps/pep-3100/>)

Python en:Installation

If you have Python 2.x installed already, you do **not** have to remove it to install Python 3.0. You can have both installed at the same time.

For Linux and BSD users

If you are using a Linux distribution such as Ubuntu, Fedora, OpenSUSE or {put your choice here}, or a BSD system such as FreeBSD, then it is most likely you already have Python installed on your system.

To test if you have Python already installed on your Linux box, open a shell program (like `konsole` or `gnome-terminal`) and enter the command `python -V` as shown below.

```
$ python -V
Python 3.0b1
```

Note

\$ is the prompt of the shell. It will be different for you depending on the settings of your OS, hence I will indicate the prompt by just the \$ symbol.

If you see some version information like the one shown above, then you have Python installed already.

However, if you get a message like this one:

```
$ python -V
bash: Python: command not found
```

Then you don't have Python installed. This is highly unlikely but possible.

Note

If you have Python 2.x already installed, then try `python3 -V`.

In this case, you have two ways of installing Python on your system.

- You can compile Python from the source code (<http://www.python.org/download/releases/3.0/>) and install it. The compilation instructions are provided at the website.
- [This option will be available after the final release of Python 3.0] Install the binary packages using the package management software that comes with your OS, such as `apt-get` in Ubuntu/Debian and other Debian-based Linux, `yum` in Fedora Linux, `pkg_add` in FreeBSD, etc. Note that you will need an internet connection to use this method. Alternatively, you can download the binaries from somewhere else and then copy to your PC and install it.

For Windows Users

Visit <http://www.python.org/download/releases/3.0/> and download the latest version from this website, which was 3.0 beta 1 (<http://www.python.org/ftp/python/3.0/python-3.0b1.msi>) as of this writing. This is just 12.8 MB which is very compact compared to most other languages or software. The installation is just like any other Windows-based software.

Caution

When you are given the option of unchecking any "optional" components, don't uncheck any! Some of these components can be useful for you, especially IDLE.

An interesting fact is that majority of Python downloads are by Windows users. Of course, this doesn't give the complete picture since almost all Linux users will have Python installed already on their systems by default.

DOS Prompt

If you want to be able to use Python from the Windows command line i.e. the DOS prompt, then you need to set the PATH variable appropriately.

For Windows 2000, XP, 2003 , click on Control Panel -> System -> Advanced -> Environment Variables. Click on the variable named **PATH** in the 'System Variables' section, then select Edit and add ;C:\Python30 to the end of what is already there. Of course, use the appropriate directory name.

For older versions of Windows, add the following line to the file C:\AUTOEXEC.BAT : 'PATH=%PATH%;C:\Python30' (without the quotes) and restart the system. For Windows NT, use the AUTOEXEC.NT file.

For Mac OS X Users

Mac OS X Users will find Python already installed on their system. Open the Terminal.app and run `python -V` and follow the advice in the above Linux section.

Summary

For a Linux system, you most probably already have Python installed on your system. Otherwise, you can install it using the package management software that comes with your distribution. For a Windows system, installing Python is as easy as downloading the installer and double-clicking on it. From now on, we will assume that you have Python installed on your system.

Next, we will write our first Python program.

Python en:First Steps

Introduction

We will now see how to run a traditional 'Hello World' program in Python. This will teach you how to write, save and run Python programs.

There are two ways of using Python to run your program - using the interactive interpreter prompt or using a source file. We will now see how to use both of these methods

Using The Interpreter Prompt

Start the interpreter on the command line by entering `python` at the shell prompt.

For Windows users, you can run the interpreter in the command line if you have set the `PATH` variable appropriately.

If you are using IDLE, click on Start → Programs → Python 3.0 → IDLE (Python GUI).

Now enter `print('Hello World')` followed by the Enter key. You should see the words Hello World as output.

```
$ python
Python 3.0b2 (r30b2:65106, Jul 18 2008, 18:44:17) [MSC v.1500 32
bit (Intel)] on win32
Type "help", "copyright", "credits" or "license" for more
information.
>>> print('Hello World')
Hello World
>>>
```

Notice that Python gives you the output of the line immediately! What you just entered is a single Python *statement*. We use `print` to (unsurprisingly) print any value that you supply to it. Here, we are supplying the text Hello World and this is promptly printed to the screen.

How to Quit the Interpreter Prompt

To exit the prompt, press `ctrl-d` if you are using IDLE or are using a Linux/BSD shell.

In case of the Windows command prompt, press `ctrl-z` followed by enter key.

Choosing An Editor

Before we move on to writing Python programs in source files, we need an editor to write the source files. The choice of an editor is crucial indeed. You have to choose an editor as you would choose a car you would buy. A good editor will help you write Python programs easily, making your journey more comfortable and helps you reach your destination (achieve your goal) in a much faster and safer way.

One of the very basic requirements is **syntax highlighting** where all the different parts of your Python program are colorized so that you can *see* your program and visualize its running.

If you are using Windows, then I suggest that you use IDLE. IDLE does syntax highlighting and a lot more such as allowing you to run your programs within IDLE among other things. A special note: **Do not use Notepad** - it is a bad choice because it does not do syntax highlighting and also importantly it does not support indentation of the text which is very important in our case as we will see later. Good editors such as IDLE (and also VIM) will automatically help you do this.

If you are using Linux/FreeBSD, then you have a lot of choices for an editor. If you are just beginning to program, you might want to use geany. It has a graphical user interface and has buttons to compile and run your python program without a fuss.

If you are an experienced programmer, then you must be already using Vim or Emacs. Needless to say, these are two of the most powerful editors and you will be benefitted by using them to write your Python programs. I personally use Vim for most of my programs. If you are a beginner programmer, then you can use Kate which is one of my favorites. In case you are willing to take the time to learn Vim or Emacs, then I highly recommend that you do learn to use either of them as it will be very useful for you in the long run.

In this book, we will use **IDLE**, our IDE and editor of choice. IDLE is installed by default with the Windows and Mac OS X Python installers. It is also available for installation for Linux (<http://love-python.blogspot.com/2008/03/install-idle-in-linux.html>) and BSDs in their respective repositories.

We will explore how to use IDLE in the next section. For further details, please refer the IDLE documentation (<http://www.python.org/idle/doc/idlemain.html>).

If you still want to explore other choices of an editor, see the comprehensive list of Python editors (<http://www.python.org/cgi-bin/moinmoin/PythonEditors>) and make your choice. You can also choose an IDE (Integrated Development Environment) for Python. See the comprehensive list of IDEs that support Python (<http://www.python.org/cgi-bin/moinmoin/IntegratedDevelopmentEnvironments>) for more details. Once you start writing large Python programs, IDEs can be very useful indeed.

I repeat once again, please choose a proper editor - it can make writing Python programs more fun and easy.

For Vim users

There is a good introduction on how to make Vim a powerful Python IDE by John M Anderson (<http://blog.sontek.net/2008/05/11/python-with-a-modular-ide-vim/>).

For Emacs users

There is a good introduction on how to make Emacs a powerful Python IDE by Ryan McGuire (<http://www.enigmacurry.com/2008/05/09/emacs-as-a-powerful-python-ide/>).

Using A Source File

Now let's get back to programming. There is a tradition that whenever you learn a new programming language, the first program that you write and run is the 'Hello World' program - all it does is just say 'Hello World' when you run it. As Simon Cozens ^[1] puts it, it is the 'traditional incantation to the programming gods to help you learn the language better' :).

Start your choice of editor, enter the following program and save it as `helloworld.py`

If you are using IDLE, click on File → New Window and enter the following program. Then click on File → Save.

```
#!/usr/bin/python
#Filename: helloworld.py

print('Hello World')
```

Run this program by opening a shell (Linux terminal or DOS prompt) and entering the command `python helloworld.py`.

If you are using IDLE, use the menu Run → Run Module or the keyboard shortcut F5.

The output is as shown below.

```
$ python helloworld.py
Hello World
```

If you got the output as shown above, congratulations! - you have successfully run your first Python program.

In case you got an error, please type the above program *exactly* as shown and above and run the program again. Note that Python is case-sensitive i.e. `print` is not the same as `Print` - note the lowercase `p` in the former and the uppercase `P` in the latter. Also, ensure there are no spaces or tabs before the first character in each line - we will see why this is important later.

How It Works

Let us consider the first two lines of the program. These are called *comments* - anything to the right of the `#` symbol is a comment and is mainly useful as notes for the reader of the program.

Python does not use comments except for the special case of the first line here. It is called the **shebang line** - whenever the first two characters of the source file are `#!` followed by the location of a program, this tells your Linux/Unix system that this program should be run with this interpreter when you execute the program. This is explained in detail in the next section. Note that you can always run the program on any platform by specifying the interpreter directly on the command line such as the command `python helloworld.py`.

Important

Use comments sensibly in your program to explain some important details of your program - this is useful for readers of your program so that they can easily understand what the program is doing. Remember, that person can be yourself after six months!

The comments are followed by a Python *statement*. Here we call the `print` function this just prints the text 'Hello World'. We will learn about functions in a → later chapter, what

you should understand now is that whatever you supply in the parentheses will be printed back to the screen. In this case, we supply 'Hello World' which is referred to as a string - don't worry, we will explore these terminologies in detail later.

Executable Python Programs

This applies only to Linux/Unix users but Windows users might be curious as well about the first line of the program. First, we have to give the program executable permission using the `chmod` command then *run* the source program.

```
$ chmod a+x helloworld.py
$ ./helloworld.py
Hello World
```

The `chmod` command is used here to *change* the *mode* of the file by giving execute permission to *all* users of the system. Then, we execute the program directly by specifying the location of the source file. We use the `./` to indicate that the program is located in the current directory.

To make things more fun, you can rename the file to just `helloworld` and run it as `./helloworld` and it will still work since the system knows that it has to run the program using the interpreter whose location is specified in the first line in the source file.

What if you don't know where Python is located? Then, you can use the special `env` program on Linux/Unix systems. Just change the first line of the program to the following:

```
#!/usr/bin/env python
```

The `env` program will in turn look for the Python interpreter which will run the program.

So far, we have been able to run our program as long as we know the exact path. What if we wanted to be able to run the program from anywhere? You can do this by storing the program in one of the directories listed in the `PATH` environment variable. Whenever you run any program, the system looks for that program in each of the directories listed in the `PATH` environment variable and then runs that program. We can make this program available everywhere by simply copying this source file to one of the directories listed in `PATH`.

```
$ echo $PATH
/usr/local/bin:/usr/bin:/bin:/usr/X11R6/bin:/home/swaroop/bin
$ cp helloworld.py /home/swaroop/bin/helloworld
$ helloworld
Hello World
```

We can display the `PATH` variable using the `echo` command and prefixing the variable name by `$` to indicate to the shell that we need the value of this variable. We see that `/home/swaroop/bin` is one of the directories in the `PATH` variable where *swaroop* is the username I am using in my system. There will usually be a similar directory for your username on your system. Alternatively, you can add a directory of your choice to the `PATH` variable - this can be done by running `PATH=$PATH:/home/swaroop/mydir` where `'/home/swaroop/mydir'` is the directory I want to add to the `PATH` variable.

This method is very useful if you want to write useful scripts that you want to run the program anytime, anywhere. It is like creating your own commands just like `cd` or any

other commands that you use in the Linux terminal or DOS prompt.

Caution

W.r.t. Python, a program or a script or software all mean the same thing.

Getting Help

If you need quick information about any function or statement in Python, then you can use the built-in help functionality. This is very useful especially when using the interpreter prompt. For example, run `help(print)` - this displays the help for the print function which is used to print things to the screen.

Note

Press `q` to exit the help.

Similarly, you can obtain information about almost anything in Python. Use `help()` to learn more about using help itself!

In case you need to get help for operators like `return`, then you need to put those inside quotes such as `help('return')` so that Python doesn't get confused on what we're trying to do.

Summary

You should now be able to write, save and run Python programs at ease. Now that you are a Python user, let's learn some more Python concepts.

Python en:Basics

Just printing 'Hello World' is not enough, is it? You want to do more than that - you want to take some input, manipulate it and get something out of it. We can achieve this in Python using constants and variables.

Literal Constants

An example of a literal constant is a number like 5, 1.23, 9.25e-3 or a string like 'This is a string' or "It's a string!". It is called a literal because it is *literal* - you use its value literally. The number 2 always represents itself and nothing else - it is a *constant* because its value cannot be changed. Hence, all these are referred to as literal constants.

Numbers

Numbers in Python are of three types - integers, floating point and complex numbers.

- An examples of an integer is 2 which is just a whole number.
- Examples of floating point numbers (or *floats* for short) are 3.23 and 52.3E-4. The E notation indicates powers of 10. In this case, 52.3E-4 means $52.3 * 10^{-4}$.
- Examples of complex numbers are (-5+4j) and (2.3 - 4.6j)

Note for Experienced Programmers

There is no separate 'long int' type. The default integer type can be any large value.

Strings

A string is a *sequence* of *characters*. Strings are basically just a bunch of words. The words can be in English or any other language that is supported in the Unicode standard, which means almost any language in the world (http://www.unicode.org/faq/basic_q.html#16).

Note for Experienced Programmers

There are no "ASCII-only" strings because Unicode is a superset of ASCII. If a strictly ASCII-encoded byte-stream is needed, then use `str.encode("ascii")`. For more details, please see the related discussion at StackOverflow (<http://stackoverflow.com/questions/175240/how-do-i-convert-a-files-format-from-unicode-to-ascii-using-python#175270>).

By default, all strings are in Unicode.

I can almost guarantee that you will be using strings in almost every Python program that you write, so pay attention to the following part on how to use strings in Python.

Single Quotes

You can specify strings using single quotes such as 'Quote me on this'. All white space i.e. spaces and tabs are preserved as-is.

Double Quotes

Strings in double quotes work exactly the same way as strings in single quotes. An example is "What's your name?"

Triple Quotes

You can specify **multi-line strings** using triple quotes - (""" or '''). You can use single quotes and double quotes freely within the triple quotes. An example is:

```
'''This is a multi-line string. This is the first line.
This is the second line.
"What's your name?," I asked.
He said "Bond, James Bond."
'''
```

Escape Sequences

Suppose, you want to have a string which contains a single quote ('), how will you specify this string? For example, the string is What's your name?. You cannot specify 'What's your name?' because Python will be confused as to where the string starts and ends. So, you will have to specify that this single quote does not indicate the end of the string. This can be done with the help of what is called an *escape sequence*. You specify the single quote as \' - notice the backslash. Now, you can specify the string as 'What\'s your name?'.

Another way of specifying this specific string would be "What's your name?" i.e. using double quotes. Similarly, you have to use an escape sequence for using a double quote itself in a double quoted string. Also, you have to indicate the backslash itself using the escape sequence \\\.

What if you wanted to specify a two-line string? One way is to use a triple-quoted string as shown previously or you can use an escape sequence for the newline character - \n to indicate the start of a new line. An example is This is the first line\nThis is the second line. Another useful escape sequence to know is the tab - \t. There are many more escape sequences but I have mentioned only the most useful ones here.

One thing to note is that in a string, a single backslash at the end of the line indicates that the string is continued in the next line, but no newline is added. For example:

```
"This is the first sentence.\nThis is the second sentence."
```

is equivalent to "This is the first sentence. This is the second sentence.".

Raw Strings

If you need to specify some strings where no special processing such as escape sequences are handled, then what you need is to specify a **raw string** by **prefixing r or R to the string**. An example is `r"Newlines are indicated by \n"`.

Strings Are Immutable

This means that once you have created a string, you cannot change it. Although this might seem like a bad thing, it really isn't. We will see why this is not a limitation in the various programs that we see later on.

String Literal Concatenation

If you place two string literals side by side, they are automatically concatenated by Python. For example, `'What\'s ' 'your name?'` is automatically converted in to `"What's your name?"`.

Note for C/C++ Programmers

There is no separate char data type in Python. There is no real need for it and I am sure you won't miss it.

Note for Perl/PHP Programmers

Remember that single-quoted strings and double-quoted strings are the same - they do not differ in any way.

Note for Regular Expression Users

Always use raw strings when dealing with regular expressions. Otherwise, a lot of backwhacking may be required. For example, backreferences can be referred to as `'\\1'` or `r'\\1'`.

The format Method

Sometimes we may want to construct strings from other information. This is where the `format()` method is useful.

```
#!/usr/bin/python
# Filename: str_format.py

age = 25
name = 'Swaroop'

print('{0} is {1} years old'.format(name, age))
print('Why is {0} playing with that python?'.format(name))
```

Output:

```
$ python str_format.py
Swaroop is 25 years old
Why is Swaroop playing with that python?
```

How It Works:

A string can use certain specifications and subsequently, the *format* method can be called to substitute those specifications with corresponding arguments to the *format* method.

Observe the first usage where we use `{0}` and this corresponds to the variable name which is the first argument to the format method. Similarly, the second specification is `{1}` corresponding to `age` which is the second argument to the format method.

Notice that we could achieved the same using string concatenation: `name + ' is ' + str(age) + ' years old'` but notice how much uglier and error-prone this is. **Second**, the conversion to string would be done automatically by the format method instead of the explicit conversion here. **Third**, when using the format method, we can change the message without having to deal with the variables used and vice-versa.

What Python does in the format method is that it substitutes each argument value into the place of the specification. There can be more detailed specifications such as:

```
>>> '{0:.3}'.format(1/3) # decimal (.) precision of 3 for float
'0.333'
>>> '{0:_^11}'.format('hello') # fill with underscores (_) with the text
centered (^) to 11 width
'__hello__'
>>> '{name} wrote {book}'.format(name='Swaroop', book='A Byte of Python')
# keyword-based
'Swaroop wrote A Byte of Python'
```

Details of this formatting specification is explained in the Python Enhancement Proposal No. 3101 (<http://www.python.org/dev/peps/pep-3101/>).

Variables

Using just literal constants can soon become boring - we need some way of storing any information and manipulate them as well. This is where *variables* come into the picture. Variables are exactly what the name implies - their value can vary, i.e., you can store anything using a variable. Variables are just parts of your computer's memory where you store some information. Unlike literal constants, you need some method of accessing these variables and hence you give them names.

Identifier Naming

Variables are examples of identifiers. *Identifiers* are names given to identify *something*. There are some rules you have to follow for naming identifiers:

- The first character of the identifier must be a letter of the alphabet (uppercase ASCII or lowercase ASCII or Unicode character) or an underscore ('_').
- The rest of the identifier name can consist of letters (uppercase ASCII or lowercase ASCII or Unicode character), underscores ('_') or digits (0-9).
- Identifier names are case-sensitive. For example, `myname` and `myName` are **not** the same. Note the lowercase `n` in the former and the uppercase `N` in the latter.
- Examples of *valid* identifier names are `i`, `__my_name`, `name_23`, `a1b2_c3` and `resumÃfÆ'Ã+â€"Ãfâ€ Ãâ, -â,,çÃfÆ'Ãçâ, -ÃiÃfâ€šÃ, Â©_count`.
- Examples of *invalid* identifier names are `2things`, `this is spaced out`, `my-name`, and `"this_is_in_quotes"`.

Data Types

Variables can hold values of different types called **data types**. The basic types are numbers and strings, which we have already discussed. In later chapters, we will see how to create our own types using classes.

Objects

Remember, Python refers to anything used in a program as an *object*. This is meant in the generic sense. Instead of saying 'the *something*', we say 'the *object*'.

Note for Object Oriented Programming users

Python is **strongly** object-oriented in the sense that **everything is an object including numbers, strings and functions.**

We will now see how to use variables along with literal constants. Save the following example and run the program.

How to write Python programs

Henceforth, the standard procedure to save and run a Python program is as follows:

1. Open your favorite editor.
1. Enter the program code given in the example.
1. Save it as a file with the filename mentioned in the comment. I follow the convention of having all Python programs saved with the extension `.py`.
1. Run the interpreter with the command `python program.py` or use IDLE to run the programs. You can also use the executable method as explained earlier.

Example: Using Variables And Literal Constants

```
# Filename : var.py

i = 5
print(i)
i = i + 1
print(i)

s = '''This is a multi-line string.
This is the second line.'''
print(s)
```

Output:

```
$ python var.py
5
6
This is a multi-line string.
This is the second line.
```

How It Works:

Here's how this program works. First, we assign the literal constant value 5 to the variable `i` using the assignment operator (`=`). This line is called a statement because it states that

something should be done and in this case, we connect the variable name `i` to the value 5. Next, we print the value of `i` using the `print` statement which, unsurprisingly, just prints the value of the variable to the screen.

Then we add 1 to the value stored in `i` and store it back. We then print it and expectedly, we get the value 6.

Similarly, we assign the literal string to the variable `s` and then print it.

Note for static language programmers

Variables are used by just assigning them a value. No declaration or data type definition is needed/used.

Logical And Physical Lines

A physical line is what you *see* when you write the program. A logical line is what *Python* sees as a single statement. Python implicitly assumes that each *physical line* corresponds to a *logical line*.

An example of a logical line is a statement like `print('Hello World')` - if this was on a line by itself (as you see it in an editor), then this also corresponds to a physical line.

Implicitly, Python encourages the use of a single statement per line which makes code more readable.

If you want to specify more than one logical line on a single physical line, then you have to explicitly specify this using a semicolon (;) which indicates the end of a logical line/statement. For example,

```
i = 5
print(i)
```

is effectively same as

```
i = 5;
print(i);
```

and the same can be written as

```
i = 5; print(i);
```

or even

```
i = 5; print(i)
```

However, I **strongly recommend** that you stick to **writing a single logical line in a single physical line only**. Use more than one physical line for a single logical line only if the logical line is really long. The idea is to avoid the semicolon as much as possible since it leads to more readable code. In fact, I have *never* used or even seen a semicolon in a Python program.

An example of writing a logical line spanning many physical lines follows. This is referred to as **explicit line joining**.

```
s = 'This is a string. \
This continues the string.'
print(s)
```

This gives the output:

```
This is a string. This continues the string.
```

Similarly,

```
print\  
(i)
```

is the same as

```
print(i)
```

Sometimes, there is an implicit assumption where you don't need to use a backslash. This is the case where the logical line uses parentheses, square brackets or curly braces. This is called **implicit line joining**. You can see this in action when we write programs using lists in later chapters.

Indentation

Whitespace is important in Python. Actually, **whitespace at the beginning of the line is important**. This is called **indentation**. Leading whitespace (spaces and tabs) at the beginning of the logical line is used to determine the indentation level of the logical line, which in turn is used to determine the grouping of statements.

This means that statements which go together **must** have the same indentation. Each such set of statements is called a **block**. We will see examples of how blocks are important in later chapters.

One thing you should remember is that wrong indentation can give rise to errors. For example:

```
i = 5  
print('Value is ', i) # Error! Notice a single space at the start of  
the line  
print('I repeat, the value is ', i)
```

When you run this, you get the following error:

```
File "whitespace.py", line 4  
    print('Value is ', i) # Error! Notice a single space at the  
start of the line  
    ^  
IndentationError: unexpected indent
```

Notice that there is a single space at the beginning of the second line. The error indicated by Python tells us that the syntax of the program is invalid i.e. the program was not properly written. What this means to you is that *you cannot arbitrarily start new blocks of statements* (except for the default main block which you have been using all along, of course). Cases where you can use new blocks will be detailed in later chapters such as the control flow chapter.

How to indent

Do **not** use a mixture of tabs and spaces for the indentation as it does not work across different platforms properly. I *strongly recommend* that you use a *single tab* or *four*

spaces for each indentation level.

Choose either of these two indentation styles. More importantly, choose one and use it **consistently** i.e. use that indentation style *only*.

Note to static language programmers

Python will always use indentation for blocks and will never use braces. Run from `__future__ import braces` to learn more.

Summary

Now that we have gone through many nitty-gritty details, we can move on to more interesting stuff such as control flow statements. Be sure to become comfortable with what you have read in this chapter.

Python en:Operators and Expressions

Introduction

Most statements (logical lines) that you write will contain **expressions**. A simple example of an expression is `2 + 3`. An expression can be broken down into operators and operands.

Operators are functionality that do something and can be represented by symbols such as `+` or by special keywords. Operators require some data to operate on and such data is called *operands*. In this case, 2 and 3 are the operands.

Operators

We will briefly take a look at the operators and their usage:

Note that you can evaluate the expressions given in the examples using the interpreter interactively. For example, to test the expression `2 + 3`, use the interactive Python interpreter prompt:

```
>>> 2 + 3
5
>>> 3 * 5
15
>>>
```

Operator	Name	Explanation	Examples
<code>+</code>	Plus	Adds the two objects	<code>3 + 5</code> gives 8. <code>'a' + 'b'</code> gives <code>'ab'</code> .
<code>-</code>	Minus	Either gives a negative number or gives the subtraction of one number from the other	<code>-5.2</code> gives a negative number. <code>50 - 24</code> gives 26.

*	Multiply	Gives the multiplication of the two numbers or returns the string repeated that many times.	2 * 3 gives 6. 'la' * 3 gives 'lalala'.
**	Power	Returns x to the power of y	3 ** 4 gives 81 (i.e. 3 * 3 * 3 * 3)
/	Divide	Divide x by y	4 / 3 gives 1.3333333333333333.
//	Floor Division	Returns the floor of the quotient	4 // 3 gives 1.
%	Modulo	Returns the remainder of the division	8 % 3 gives 2. -25.5 % 2.25 gives 1.5.
<<	Left Shift	Shifts the bits of the number to the left by the number of bits specified. (Each number is represented in memory by bits or binary digits i.e. 0 and 1)	2 << 2 gives 8. 2 is represented by 10 in bits. Left shifting by 2 bits gives 1000 which represents the decimal 8.
>>	Right Shift	Shifts the bits of the number to the right by the number of bits specified.	11 >> 1 gives 5. 11 is represented in bits by 1011 which when right shifted by 1 bit gives 101 which is the decimal 5.
&	Bitwise AND	Bitwise AND of the numbers	5 & 3 gives 1.
	Bit-wise OR	Bitwise OR of the numbers	5 3 gives 7
^	Bit-wise XOR	Bitwise XOR of the numbers	5 ^ 3 gives 6
~	Bit-wise invert	The bit-wise inversion of x is -(x+1)	~5 gives -6.
<	Less Than	Returns whether x is less than y. All comparison operators return True or False. Note the capitalization of these names.	5 < 3 gives False and 3 < 5 gives True. Comparisons can be chained arbitrarily: 3 < 5 < 7 gives True.
>	Greater Than	Returns whether x is greater than y	5 > 3 returns True. If both operands are numbers, they are first converted to a common type. Otherwise, it always returns False.
<=	Less Than or Equal To	Returns whether x is less than or equal to y	x = 3; y = 6; x <= y returns True.
>=	Greater Than or Equal To	Returns whether x is greater than or equal to y	x = 4; y = 3; x >= 3 returns True.
==	Equal To	Compares if the objects are equal	x = 2; y = 2; x == y returns True. x = 'str'; y = 'stR'; x == y returns False. x = 'str'; y = 'str'; x == y returns True.
!=	Not Equal To	Compares if the objects are not equal	x = 2; y = 3; x != y returns True.
not	Boolean NOT	If x is True, it returns False. If x is False, it returns True.	x = True; not x returns False.
and	Boolean AND	x and y returns False if x is False, else it returns evaluation of y	x = False; y = True; x and y returns False since x is False. In this case, Python will not evaluate y since it knows that the left hand side of the 'and' expression is False which implies that the whole expression will be False irrespective of the other values. This is called short-circuit evaluation.

or	Boolean OR	If x is True, it returns True, else it returns evaluation of y	x = True; y = False; x or y returns True. Short-circuit evaluation applies here as well.
----	------------	--	--

Shortcut for math operation and assignment

It is common to run a math operation on a variable and then assign the result of the operation back to the variable, hence there is a shortcut for such expressions:

You can write:

```
a = 2; a = a * 3
```

as:

```
a = 2; a *= 3
```

Notice that `var = var operation expression` becomes `var operation= expression`.

Evaluation Order

If you had an expression such as `2 + 3 * 4`, is the addition done first or the multiplication? Our high school maths tells us that the multiplication should be done first. This means that the multiplication operator has higher precedence than the addition operator.

The following table gives the precedence table for Python, from the lowest precedence (least binding) to the highest precedence (most binding). This means that in a given expression, Python will first evaluate the operators and expressions lower in the table before the ones listed higher in the table.

The following table, taken from the Python reference manual (<http://docs.python.org/dev/3.0/reference/expressions.html#evaluation-order>), is provided for the sake of completeness. It is far better to use parentheses to group operators and operands appropriately in order to explicitly specify the precedence. This makes the program more readable. See Changing the Order of Evaluation below for details.

Operator	Description
lambda	Lambda Expression
or	Boolean OR
and	Boolean AND
not x	Boolean NOT
in, not in	Membership tests
is, is not	Identity tests
<, <=, >, >=, !=, ==	Comparisons
	Bitwise OR
^	Bitwise XOR
&	Bitwise AND
<<, >>	Shifts
+, -	Addition and subtraction
*, /, //, %	Multiplication, Division, Floor Division and Remainder
+x, -x	Positive, Negative

<code>~x</code>	Bitwise NOT
<code>**</code>	Exponentiation
<code>x.attribute</code>	Attribute reference
<code>x[index]</code>	Subscription
<code>x[index1:index2]</code>	Slicing
<code>f(arguments ...)</code>	Function call
<code>(expressions, ...)</code>	Binding or tuple display
<code>[expressions, ...]</code>	List display
<code>{key:datum, ...}</code>	Dictionary display

The operators which we have not already come across will be explained in later chapters.

Operators with the *same precedence* are listed in the same row in the above table. For example, `+` and `-` have the same precedence.

Changing the Order Of Evaluation

To make the expressions more readable, we can use parentheses. For example, `2 + (3 * 4)` is definitely easier to understand than `2 + 3 * 4` which requires knowledge of the operator precedences. As with everything else, the parentheses should be used reasonably (do not overdo it) and should not be redundant (as in `2 + (3 + 4)`).

There is an additional advantage to using parentheses - it helps us to change the order of evaluation. For example, if you want addition to be evaluated before multiplication in an expression, then you can write something like `(2 + 3) * 4`.

Associativity

Operators are usually associated from left to right i.e. operators with same precedence are evaluated in a left to right manner. For example, `2 + 3 + 4` is evaluated as `(2 + 3) + 4`. Some operators like assignment operators have right to left associativity i.e. `a = b = c` is treated as `a = (b = c)`.

Expressions

Example:

```
#!/usr/bin/python
# Filename: expression.py

length = 5
breadth = 2

area = length * breadth
print('Area is', area)
print('Perimeter is', 2 * (length + breadth))
```

Output:

```
$ python expression.py
Area is 10
Perimeter is 14
```

How It Works:

The length and breadth of the rectangle are stored in variables by the same name. We use these to calculate the area and perimeter of the rectangle with the help of expressions. We store the result of the expression `length * breadth` in the variable `area` and then print it using the `print` function. In the second case, we directly use the value of the expression `2 * (length + breadth)` in the `print` function.

Also, notice how Python 'pretty-prints' the output. Even though we have not specified a space between 'Area is' and the variable `area`, Python puts it for us so that we get a clean nice output and the program is much more readable this way (since we don't need to worry about spacing in the strings we use for output). This is an example of how Python makes life easy for the programmer.

Summary

We have seen how to use operators, operands and expressions - these are the basic building blocks of any program. Next, we will see how to make use of these in our programs using statements.

Python en:Control Flow

Introduction

In the programs we have seen till now, there has always been a series of statements and Python faithfully executes them in the same order. What if you wanted to change the flow of how it works? For example, you want the program to take some decisions and do different things depending on different situations such as printing 'Good Morning' or 'Good Evening' depending on the time of the day?

As you might have guessed, this is achieved using control flow statements. There are three control flow statements in Python - `if`, `for` and `while`.

The if statement

The `if` statement is used to check a condition and *if* the condition is true, we run a block of statements (called the *if-block*), *else* we process another block of statements (called the *else-block*). The *else* clause is optional.

Example:

```
#!/usr/bin/python
# Filename: if.py

number = 23
guess = int(input('Enter an integer : '))

if guess == number:
    print('Congratulations, you guessed it.') # New block starts here
    print('(but you do not win any prizes!)') # New block ends here
elif guess < number:
    print('No, it is a little higher than that') # Another block
    # You can do whatever you want in a block ...
else:
    print('No, it is a little lower than that')
    # you must have guess > number to reach here

print('Done')
# This last statement is always executed, after the if statement is
executed
```

Output:

```
$ python if.py
Enter an integer : 50
No, it is a little lower than that
Done

$ python if.py
Enter an integer : 22
```

```
No, it is a little higher than that
Done

$ python if.py
Enter an integer : 23
Congratulations, you guessed it.
(but you do not win any prizes!)
Done
```

How It Works:

In this program, we take guesses from the user and check if it is the number that we have. We set the variable `number` to any integer we want, say 23. Then, we take the user's guess using the `input()` function. Functions are just reusable pieces of programs. We'll read more about them in the next chapter.

We supply a string to the built-in `input` function which prints it to the screen and waits for input from the user. Once we enter something and press enter key, the `input()` function returns what we entered, as a string. We then convert this string to an integer using `int` and then store it in the variable `guess`. Actually, the `int` is a class but all you need to know right now is that you can use it to convert a string to an integer (assuming the string contains a valid integer in the text).

Next, we compare the guess of the user with the number we have chosen. If they are equal, we print a success message. Notice that we use indentation levels to tell Python which statements belong to which block. This is why indentation is so important in Python. I hope you are sticking to the "consistent indentation" rule. Are you?

Notice how the `if` statement contains a colon at the end - we are indicating to Python that a block of statements follows.

Then, we check if the guess is less than the number, and if so, we inform the user to guess a little higher than that. What we have used here is the `elif` clause which actually combines two related `if else-if else` statements into one combined `if-elif-else` statement. This makes the program easier and reduces the amount of indentation required.

The `elif` and `else` statements must also have a colon at the end of the logical line followed by their corresponding block of statements (with proper indentation, of course)

You can have another `if` statement inside the `if`-block of an `if` statement and so on - this is called a nested `if` statement.

Remember that the `elif` and `else` parts are optional. A minimal valid `if` statement is:

```
if True:
    print('Yes, it is true')
```

After Python has finished executing the complete `if` statement along with the associated `elif` and `else` clauses, it moves on to the next statement in the block containing the `if` statement. In this case, it is the main block where execution of the program starts and the next statement is the `print('Done')` statement. After this, Python sees the ends of the program and simply finishes up.

Although this is a very simple program, I have been pointing out a lot of things that you should notice even in this simple program. All these are pretty straightforward (and surprisingly simple for those of you from C/C++ backgrounds) and requires you to become

aware of all these initially, but after that, you will become comfortable with it and it'll feel 'natural' to you.

Note for C/C++ Programmers

There is no switch statement in Python. You can use an `if...elif...else` statement to do the same thing (and in some cases, use a dictionary to do it quickly)

The while Statement

The while statement allows you to repeatedly execute a block of statements as long as a condition is true. A while statement is an example of what is called a **looping statement**. A while statement can have an optional else clause.

Example:

```
#!/usr/bin/python
# Filename: while.py

number = 23
running = True

while running:
    guess = int(input('Enter an integer : '))

    if guess == number:
        print('Congratulations, you guessed it.')
        running = False # this causes the while loop to stop
    elif guess < number:
        print('No, it is a little higher than that.')
    else:
        print('No, it is a little lower than that.')
else:
    print('The while loop is over.')
    # Do anything else you want to do here

print('Done')
```

Output:

```
$ python while.py
Enter an integer : 50
No, it is a little lower than that.
Enter an integer : 22
No, it is a little higher than that.
Enter an integer : 23
Congratulations, you guessed it.
The while loop is over.
Done
```

How It Works:

In this program, we are still playing the guessing game, but the advantage is that the user is allowed to keep guessing until he guesses correctly - there is no need to repeatedly run the program for each guess, as we have done in the previous section. This aptly demonstrates the use of the while statement.

We move the input and if statements to inside the while loop and set the variable running to True before the while loop. First, we check if the variable running is True and then proceed to execute the corresponding *while-block*. After this block is executed, the condition is again checked which in this case is the running variable. If it is true, we execute the while-block again, else we continue to execute the optional else-block and then continue to the next statement.

The **else block is executed when the while loop condition becomes False** - this may even be the first time that the condition is checked. If there is an else clause for a while loop, it is **always executed unless you break out of the loop with a break statement**.

The True and False are called Boolean types and you can consider them to be equivalent to the value 1 and 0 respectively.

Note for C/C++ Programmers

Remember that you can have an else clause for the while loop.

The for loop

The `for..in` statement is another looping statement which *iterates* over a sequence of objects i.e. go through each item in a sequence. We will see more about sequences in detail in later chapters. What you need to know right now is that a sequence is just an ordered collection of items.

Example:

```
#!/usr/bin/python
# Filename: for.py

for i in range(1, 5):
    print(i)
else:
    print('The for loop is over')
```

Output:

```
$ python for.py
1
2
3
4
The for loop is over
```

How It Works:

In this program, we are printing a *sequence* of numbers. We generate this sequence of numbers using the **built-in range function**.

What we do here is supply it two numbers and range returns a sequence of numbers starting from the first number and up to the second number. For example, **range(1,5)**

gives the sequence [1, 2, 3, 4]. By default, range takes a step count of 1. If we supply a third number to range, then that becomes the step count. For example, range(1,5,2) gives [1,3]. Remember that the range extends *up to* the second number i.e. it does **not** include the second number.

The for loop then iterates over this range - for i in range(1,5) is equivalent to for i in [1, 2, 3, 4] which is like assigning each number (or object) in the sequence to i, one at a time, and then executing the block of statements for each value of i. In this case, we just print the value in the block of statements.

Remember that the else part is optional. When included, it is always executed once after the for loop is over unless a break statement is encountered.

Remember that the for..in loop works for any sequence. Here, we have a list of numbers generated by the built-in range function, but in general we can use any kind of sequence of any kind of objects! We will explore this idea in detail in later chapters.

Note for C/C++/Java/C# Programmers

The Python for loop is radically different from the C/C++ for loop. C# programmers will note that the for loop in Python is similar to the foreach loop in C#. Java programmers will note that the same is similar to for (int i : IntArray) in Java 1.5 .

In C/C++, if you want to write for (int i = 0; i < 5; i++), then in Python you write just for i in range(0,5). As you can see, the for loop is simpler, more expressive and less error prone in Python.

The break Statement

The break statement is used to *break* out of a loop statement i.e. stop the execution of a looping statement, even if the loop condition has not become False or the sequence of items has been completely iterated over.

An important note is that if you break out of a for or while loop, any corresponding loop else block is **not** executed.

Example:

```
#!/usr/bin/python
# Filename: break.py

while True:
    s = (input('Enter something : '))
    if s == 'quit':
        break
    print('Length of the string is', len(s))
print('Done')
```

Output:

```
$ python break.py
Enter something : Programming is fun
Length of the string is 18
Enter something : When the work is done
Length of the string is 21
```

```
Enter something : if you wanna make your work also fun:
Length of the string is 37
Enter something :      use Python!
Length of the string is 12
Enter something : quit
Done
```

How It Works:

In this program, we repeatedly take the user's input and print the length of each input each time. We are providing a special condition to stop the program by checking if the user input is 'quit'. We stop the program by *breaking* out of the loop and reach the end of the program.

The length of the input string can be found out using the **built-in len function**.

Remember that the break statement can be used with the for loop as well.

Swaroop's Poetic Python

The input I have used here is a mini poem I have written called **Swaroop's Poetic Python**:

```
Programming is fun
When the work is done
if you wanna make your work also fun:
    use Python!
```

The continue Statement

The continue statement is used to tell Python to **skip the rest of the statements in the current loop block and to *continue* to the next iteration of the loop.**

Example:

```
#!/usr/bin/python
# Filename: continue.py

while True:
    s = input('Enter something : ')
    if s == 'quit':
        break
    if len(s) < 3:
        print('Too small')
        continue
    print('Input is of sufficient length')
    # Do other kinds of processing here...
```

Output:

```
$ python test.py
Enter something : a
Too small
Enter something : 12
Too small
```

```
Enter something : abc
Input is of sufficient length
Enter something : quit
```

How It Works:

In this program, we accept input from the user, but we process them only if they are at least 3 characters long. So, we use the built-in `len` function to get the length and if the length is less than 3, we skip the rest of the statements in the block by using the `continue` statement. Otherwise, the rest of the statements in the loop are executed and we can do any kind of processing we want to do here.

Note that **the `continue` statement works with the `for` loop as well.**

Summary

We have seen how to use the three control flow statements - `if`, `while` and `for` along with their associated `break` and `continue` statements. These are some of the most often used parts of Python and hence, becoming comfortable with them is essential.

Next, we will see how to create and use functions.

Python en:Functions

Introduction

Functions are reusable pieces of programs. They allow you to give a name to a block of statements and you can run that block using that name anywhere in your program and any number of times. This is known as *calling* the function. We have already used many built-in functions such as the `len` and `range`.

The function concept is probably *the* most important building block of any non-trivial software (in any programming language), so we will explore various aspects of functions in this chapter.

Functions are **defined** using the `def` keyword. This is followed by an *identifier* name for the function followed by a pair of **parentheses** which may enclose some names of variables and the line ends with a **colon**. Next follows the block of statements that are part of this function. An example will show that this is actually very simple:

Example:

```
#!/usr/bin/python
# Filename: function1.py

def sayHello():
    print('Hello World!') # block belonging to the function
# End of function
```

```
sayHello() # call the function
sayHello() # call the function again
```

Output:

```
$ python function1.py
Hello World!
Hello World!
```

How It Works:

We define a function called `sayHello` using the syntax as explained above. This function takes no parameters and hence there are no variables declared in the parentheses. Parameters to functions are just input to the function so that we can pass in different values to it and get back corresponding results.

Notice that we can call the same function twice which means we do not have to write the same code again.

Function Parameters

A function can take parameters, which are values you supply to the function so that the function can *do* something utilising those values. These parameters are just like variables except that the values of these variables are defined when we call the function and are already assigned values when the function runs.

Parameters are specified within the pair of parentheses in the function definition, separated by commas. When we call the function, we supply the values in the same way. Note the terminology used - the names given in the function definition are called *parameters* whereas the values you supply in the function call are called *arguments*.

Example:

```
#!/usr/bin/python
# Filename: func_param.py

def printMax(a, b):
    if a > b:
        print(a, 'is maximum')
    elif a == b:
        print(a, 'is equal to', b)
    else:
        print(b, 'is maximum')

printMax(3, 4) # directly give literal values

x = 5
y = 7

printMax(x, y) # give variables as arguments
```

Output:

```
$ python func_param.py
4 is maximum
7 is maximum
```

How It Works:

Here, we define a function called `printMax` where we take two parameters called `a` and `b`. We find out the greater number using a simple `if..else` statement and then print the bigger number.

In the first usage of `printMax`, we directly supply the numbers i.e. arguments. In the second usage, we call the function using variables. `printMax(x, y)` causes value of argument `x` to be assigned to parameter `a` and the value of argument `y` assigned to parameter `b`. The `printMax` function works the same in both the cases.

Local Variables

When you declare variables inside a function definition, they are not related in any way to other variables with the same names used outside the function i.e. variable names are *local* to the function. This is called the *scope* of the variable. All variables have the scope of the block they are declared in starting from the point of definition of the name.

Example:

```
#!/usr/bin/python
# Filename: func_local.py

x = 50

def func(x):
    print('x is', x)
    x = 2
    print('Changed local x to', x)

func(x)
print('x is still', x)
```

Output:

```
$ python func_local.py
x is 50
Changed local x to 2
x is still 50
```

How It Works:

In the function, the first time that we use the *value* of the name `x`, Python uses the value of the parameter declared in the function.

Next, we assign the value 2 to `x`. The name `x` is local to our function. So, when we change the value of `x` in the function, the `x` defined in the main block remains unaffected.

In the last print function call, we display the value of `x` in the main block and confirm that it is actually unaffected.

Using The global Statement

If you want to assign a value to a name defined at the top level of the program (i.e. not inside any kind of scope such as functions or classes), then you have to tell Python that the name is not local, but it is *global*. We do this using the `global` statement. It is impossible to assign a value to a variable defined outside a function without the `global` statement.

You can use the values of such variables defined outside the function (assuming there is no variable with the same name within the function). However, this is not encouraged and should be avoided since it becomes unclear to the reader of the program as to where that variable's definition is. Using the `global` statement makes it amply clear that the variable is defined in an outermost block.

Example:

```
#!/usr/bin/python
# Filename: func_global.py

x = 50

def func():
    global x

    print('x is', x)
    x = 2
    print('Changed global x to', x)

func()
print('Value of x is', x)
```

Output:

```
$ python func_global.py
x is 50
Changed global x to 2
Value of x is 2
```

How It Works:

The `global` statement is used to declare that `x` is a global variable - hence, when we assign a value to `x` inside the function, that change is reflected when we use the value of `x` in the main block.

You can specify more than one global variable using the same `global` statement. For example, `global x, y, z`.

Using nonlocal statement

We have seen how to access variables in the local and global scope above. There is another kind of scope called "nonlocal" scope which is in-between these two types of scopes.

Nonlocal scopes are observed when you define functions inside functions.

Since everything in Python is just executable code, you can define functions anywhere.

Let's take an example:

```
#!/usr/bin/python
# Filename: func_nonlocal.py

def func_outer():
    x = 2
    print('x is', x)

    def func_inner():
        nonlocal x
        x = 5

    func_inner()
    print('Changed local x to', x)

func_outer()
```

Output:

```
$ python func_nonlocal.py
x is 2
Changed local x to 5
```

How It Works:

When we are inside `func_inner`, the 'x' defined in the first line of `func_outer` is relatively neither in local scope nor in global scope. We declare that we are using this x by `nonlocal x` and hence we get access to that variable.

Try changing the `nonlocal x` to `global x` and also by removing the statement itself and observe the difference in behavior in these two cases.

Default Argument Values

For some functions, you may want to make some of its parameters as *optional* and use default values if the user does not want to provide values for such parameters. This is done with the help of default argument values. You can specify default argument values for parameters by following the parameter name in the function definition with the assignment operator (=) followed by the default value.

Note that the default argument value should be a constant. More precisely, the default argument value should be immutable - this is explained in detail in later chapters. For now, just remember this.

Example:

```
#!/usr/bin/python
# Filename: func_default.py

def say(message, times = 1):
    print(message * times)

say('Hello')
say('World', 5)
```

Output:

```
$ python func_default.py
Hello
WorldWorldWorldWorldWorld
```

How It Works:

The function named `say` is used to print a string as many times as specified. If we don't supply a value, then by default, the string is printed just once. We achieve this by specifying a default argument value of 1 to the parameter `times`.

In the first usage of `say`, we supply only the string and it prints the string once. In the second usage of `say`, we supply both the string and an argument 5 stating that we want to say the string message 5 times.

Important

Only those parameters which are at the end of the parameter list can be given default argument values i.e. you cannot have a parameter with a default argument value before a parameter without a default argument value in the order of parameters declared in the function parameter list.

This is because the values are assigned to the parameters by position. For example, `def func(a, b=5)` is valid, but `def func(a=5, b)` is *not valid*.

Keyword Arguments

If you have some functions with many parameters and you want to specify only some of them, then you can give values for such parameters by naming them - this is called *keyword arguments* - we use the name (keyword) instead of the position (which we have been using all along) to specify the arguments to the function.

There are two *advantages* - one, using the function is easier since we do not need to worry about the order of the arguments. Two, we can give values to only those parameters which we want, provided that the other parameters have default argument values.

Example:

```
#!/usr/bin/python
# Filename: func_key.py

def func(a, b=5, c=10):
    print('a is', a, 'and b is', b, 'and c is', c)

func(3, 7)
```

```
func(25, c=24)
func(c=50, a=100)
```

Output:

```
$ python func_key.py
a is 3 and b is 7 and c is 10
a is 25 and b is 5 and c is 24
a is 100 and b is 5 and c is 50
```

How It Works:

The function named `func` has one parameter without default argument values, followed by two parameters with default argument values.

In the first usage, `func(3, 7)`, the parameter `a` gets the value 3, the parameter `b` gets the value 7 and `c` gets the default value of 10.

In the second usage `func(25, c=24)`, the variable `a` gets the value of 25 due to the position of the argument. Then, the parameter `c` gets the value of 24 due to naming i.e. keyword arguments. The variable `b` gets the default value of 5.

In the third usage `func(c=50, a=100)`, we use keyword arguments completely to specify the values. Notice, that we are specifying value for parameter `c` before that for `a` even though `a` is defined before `c` in the function definition.

VarArgs parameters

TODO

Should I write about this in a later chapter since we haven't talked about lists and dictionaries yet?

Sometimes you might want to define a function that can take *any* number of parameters, this can be achieved by using the stars:

```
#!/usr/bin/python
# Filename: total.py

def total(initial=5, *numbers, **keywords):
    count = initial
    for number in numbers:
        count += number
    for key in keywords:
        count += keywords[key]
    return count

print(total(10, 1, 2, 3, vegetables=50, fruits=100))
```

Output:

```
$ python total.py
166
```

How It Works:

When we declare a **starred parameter** such as ***param**, then all the positional arguments from that point till the end are collected as a list called 'param'.

Similarly, when we declare a **double-starred parameter** such as ****param**, then all the keyword arguments from that point till the end are collected as a dictionary called 'param'.

We will explore lists and dictionaries in a later chapter.

Keyword-only Parameters

If we want to specify certain keyword parameters to be available as keyword-only and *not* as positional arguments, they can be declared after a starred parameter:

```
#!/usr/bin/python
# Filename: keyword_only.py

def total(initial=5, *numbers, vegetables):
    count = initial
    for number in numbers:
        count += number
    count += vegetables
    return count

print(total(10, 1, 2, 3, vegetables=50))
print(total(10, 1, 2, 3))
# Raises error because we have not supplied a default argument value
for 'vegetables'
```

Output:

```
$ python keyword_only.py
66
Traceback (most recent call last):
  File "test.py", line 12, in <module>
    print(total(10, 1, 2, 3))
TypeError: total() needs keyword-only argument vegetables
```

How It Works:

Declaring parameters after a starred parameter results in keyword-only arguments. If these arguments are not supplied a default value, then calls to the function will raise an error if the keyword argument is not supplied, as seen above.

If you want to have keyword-only arguments but have no need for a starred parameter, then simply use an empty star without using any name such as **def total(initial=5, *, vegetables)**.

The return Statement

The return statement is used to *return* from a function i.e. break out of the function. We can optionally *return a value* from the function as well.

Example:

```
#!/usr/bin/python
# Filename: func_return.py

def maximum(x, y):
    if x > y:
        return x
    else:
        return y

print(maximum(2, 3))
```

Output:

```
$ python func_return.py
3
```

How It Works:

The maximum function returns the maximum of the parameters, in this case the numbers supplied to the function. It uses a simple if...else statement to find the greater value and then *returns* that value.

Note that a `return` statement without a value is equivalent to `return None`. None is a special type in Python that represents nothingness. For example, it is used to indicate that a variable has no value if it has a value of None.

Every function implicitly contains a `return None` statement at the end unless you have written your own `return` statement. You can see this by running `print(someFunction())` where the function `someFunction` does not use the `return` statement such as:

```
def someFunction():
    pass
```

The `pass` statement is used in Python to indicate an empty block of statements.

Note

There is a built-in function called `max` that already implements the 'find maximum' functionality, so use this built-in function whenever possible.

DocStrings

Python has a nifty feature called *documentation strings*, usually referred to by its shorter name *docstrings*. DocStrings are an important tool that you should make use of since it helps to document the program better and makes it easier to understand. Amazingly, we can even get the docstring back from, say a function, when the program is actually running!

Example:

```
#!/usr/bin/python
# Filename: func_doc.py

def printMax(x, y):
    '''Prints the maximum of two numbers.

    The two values must be integers.'''
    x = int(x) # convert to integers, if possible
    y = int(y)

    if x > y:
        print(x, 'is maximum')
    else:
        print(y, 'is maximum')

printMax(3, 5)
print(printMax.__doc__)
```

Output:

```
$ python func_doc.py
5 is maximum
Prints the maximum of two numbers.

    The two values must be integers.
```

How It Works:

A string on the first logical line of a function is the *docstring* for that function. Note that DocStrings also apply to *modules* and *classes* which we will learn about in the respective chapters.

The *convention* followed for a docstring is a multi-line string where the first line starts with a capital letter and ends with a dot. Then the *second line is blank* followed by any detailed explanation starting from the third line. You are *strongly advised* to follow this convention for all your docstrings for all your non-trivial functions.

We can access the docstring of the *printMax* function using the `__doc__` (notice the *double underscores*) attribute (name belonging to) of the function. Just remember that Python treats *everything* as an object and this includes functions. We'll learn more about objects in the chapter on classes.

If you have used `help()` in Python, then you have already seen the usage of docstrings! What it does is just fetch the `__doc__` attribute of that function and displays it in a neat manner for you. You can try it out on the function above - just include `help(printMax)` in

your program. Remember to press the q key to exit help.

Automated tools can retrieve the documentation from your program in this manner. Therefore, I *strongly recommend* that you use docstrings for any non-trivial function that you write. The **pydoc** command that comes with your Python distribution works similarly to `help()` using docstrings.

Annotations

Functions have another advanced feature called annotations which are a nifty way of attaching additional information for each of the parameters as well as the return value. Since the Python language itself does not interpret these annotations in any way (that functionality is left to third-party libraries to interpret in any way they want), we will skip this feature in our discussion. If you are interested to read about annotations, please see the [Python Enhancement Proposal No. 3107](http://www.python.org/dev/peps/pep-3107/) ([http:// www. python. org/ dev/ peps/ pep-3107/](http://www.python.org/dev/peps/pep-3107/)).

Summary

We have seen so many aspects of functions but note that we still haven't covered all aspects of it. However, we have already covered most of what you'll use regarding Python functions on an everyday basis.

Next, we will see how to use as well as create Python modules.

Python en:Modules

Introduction

You have seen how you can reuse code in your program by defining functions once. What if you wanted to reuse a number of functions in other programs that you write? As you might have guessed, the answer is modules.

There are various methods of writing modules, but the simplest way is to create a file with a .py extension that contains functions and variables.

Another method is to write the modules in the native language in which the Python interpreter itself was written. For example, you can write modules in the C programming language (<http://docs.python.org/extending/>) and when compiled, they can be used from your Python code when using the standard Python interpreter.

A module can be *imported* by another program to make use of its functionality. This is how we can use the Python standard library as well. First, we will see how to use the standard library modules.

Example:

```
#!/usr/bin/python
# Filename: using_sys.py

import sys

print('The command line arguments are:')
for i in sys.argv:
    print(i)

print('\n\nThe PYTHONPATH is', sys.path, '\n')
```

Output:

```
$ python using_sys.py we are arguments
The command line arguments are:
using_sys.py
we
are
arguments

The PYTHONPATH is ['', 'C:\\Windows\\system32\\python30.zip',
'C:\\Python30\\DLLs', 'C:\\Python30\\lib',
'C:\\Python30\\lib\\plat-win', 'C:\\Python30',
'C:\\Python30\\lib\\site-packages']
```

How It Works:

First, we *import* the sys module using the import statement. Basically, this translates to us telling Python that we want to use this module. The sys module contains functionality related to the Python interpreter and its environment i.e. the system.

When Python executes the `import sys` statement, it looks for the `sys` module. In this case, it is one of the built-in modules, and hence Python knows where to find it.

If it was not a compiled module i.e. a module written in Python, then the Python interpreter will search for it in the directories listed in its `sys.path` variable. If the module is found, then the statements in the body of that module is run and then the module is made *available* for you to use. Note that the initialization is done only the *first* time that we import a module.

The `argv` variable in the `sys` module is accessed using the dotted notation i.e. `sys.argv`. It clearly indicates that this name is part of the `sys` module. Another advantage of this approach is that the name does not clash with any `argv` variable used in your program.

The `sys.argv` variable is a *list* of strings (lists are explained in detail in a later chapter. Specifically, the `sys.argv` contains the list of *command line arguments* i.e. the arguments passed to your program using the command line.

If you are using an IDE to write and run these programs, look for a way to specify command line arguments to the program in the menus.

Here, when we execute `python using_sys.py we are arguments, we run the module using_sys.py` with the `python` command and the other things that follow are arguments passed to the program. Python stores the command line arguments in the `sys.argv` variable for us to use.

Remember, `the name of the script running` is always the first argument in the `sys.argv` list. So, in this case we will have `'using_sys.py'` as `sys.argv[0]`, `'we'` as `sys.argv[1]`, `'are'` as `sys.argv[2]` and `'arguments'` as `sys.argv[3]`. Notice that Python starts counting from 0 and not 1.

The `sys.path` contains the list of directory names where modules are imported from. Observe that the first string in `sys.path` is empty - this empty string indicates that the current directory is also part of the `sys.path` which is same as the `PYTHONPATH` environment variable. This means that you can directly import modules located in the current directory. Otherwise, you will have to place your module in one of the directories listed in `sys.path`.

Note that the current directory is the directory from which the program is launched. Run `import os; print(os.getcwd())` to find out the current directory of your program.

Byte-compiled .pyc files

Importing a module is a relatively costly affair, so Python does some tricks to make it faster. One way is to create *byte-compiled* files with the extension `.pyc` which is an intermediate form that Python transforms the program into (remember the introduction section on how Python works?). This `.pyc` file is useful when you import the module the next time from a different program - it will be much faster since a portion of the processing required in importing a module is already done. Also, these byte-compiled files are platform-independent.

Note

These `.pyc` files are usually created in the same directory as the corresponding `.py` files. If Python does not have permission to write to files in that directory, then the `.pyc` files will not be created.

The from ...import ...statement

If you want to directly import the `argv` variable into your program (to avoid typing the `sys. every`time for it), then you can use the `from sys import argv` statement. If you want to import all the names used in the `sys` module, then you can use the `from sys import *` statement. This works for any module.

In general, you *should avoid* using this statement and use the `import` statement instead since your program will avoid name clashes and will be more readable.

A module's `__name__`

Every module has a name and statements in a module can find out the name of its module. This is handy in the particular situation of figuring out if the module is being run standalone or being imported. As mentioned previously, when a module is imported for the first time, the code in that module is executed. We can use this concept to alter the behavior of the module if the program was used by itself and not when it was imported from another module. This can be achieved using the `__name__` attribute of the module.

Example:

```
#!/usr/bin/python
# Filename: using_name.py

if __name__ == '__main__':
    print('This program is being run by itself')
else:
    print('I am being imported from another module')
```

Output:

```
$ python using_name.py
This program is being run by itself

$ python
>>> import using_name
I am being imported from another module
>>>
```

How It Works:

Every Python module has its `__name__` defined and if this is `'__main__'`, it implies that the module is being run standalone by the user and we can take appropriate actions.

Making Your Own Modules

Creating your own modules is easy, you've been doing it all along! This is because every Python program is also a module. You just have to make sure it has a `.py` extension. The following example should make it clear.

Example:

```
#!/usr/bin/python
# Filename: mymodule.py

def sayhi():
    print('Hi, this is mymodule speaking.')

__version__ = '0.1'

# End of mymodule.py
```

The above was a sample *module*. As you can see, there is nothing particularly special about compared to our usual Python program. We will next see how to use this module in our other Python programs.

Remember that the module should be placed in the same directory as the program that we import it in, or the module should be in one of the directories listed in `sys.path`.

```
#!/usr/bin/python
# Filename: mymodule_demo.py

import mymodule

mymodule.sayhi()
print('Version', mymodule.__version__)
```

Output:

```
$ python mymodule_demo.py
Hi, this is mymodule speaking.
Version 0.1
```

How It Works:

Notice that we use the same dotted notation to access members of the module. Python makes good reuse of the same notation to give the distinctive 'Pythonic' feel to it so that we don't have to keep learning new ways to do things.

Here is a version utilising the `from..import` syntax:

```
#!/usr/bin/python
# Filename: mymodule_demo2.py

from mymodule import sayhi, __version__

sayhi()
print('Version', __version__)
```

The output of `mymodule_demo2.py` is same as the output of `mymodule_demo.py`.

Notice that if there was already a `__version__` name declared in the module that imports `mymodule`, there would be a clash. This is also likely because it is common practice for each module to declare its version number using this name. Hence, it is always recommended to prefer the `import` statement even though it might make your program a little longer.

You could also use:

```
from mymodule import *
```

This will import all public names such as `sayhi` but would not import `__version__` because it starts with double underscores.

Zen of Python

One of Python's guiding principles is that "Explicit is better than Implicit". Run `import this` to learn more and see this discussion (<http://stackoverflow.com/questions/228181/zen-of-python>) which lists examples for each of the principles.

The dir function

You can use the `built-in dir function` to list the identifiers that an object defines. For example, for a module, the identifiers include the functions, classes and variables defined in that module.

When you supply a module name to the `dir()` function, it returns the list of the names defined in that module. When no argument is applied to it, it returns the list of names defined in the current module.

Example:

```
$ python
```

```
>>> import sys # get list of attributes, in this case, for the sys module
```

```
>>> dir(sys)
['__displayhook__', '__doc__', '__excepthook__', '__name__',
 '__package__', '__s
tderr__', '__stdin__', '__stdout__', '_clear_type_cache',
 '_compact_freelists',
 '_current_frames', '_getframe', 'api_version', 'argv',
 'builtin_module_names', '
byteorder', 'call_tracing', 'callstats', 'copyright', 'displayhook',
 'dllhandle'
, 'dont_write_bytecode', 'exc_info', 'excepthook', 'exec_prefix',
 'executable',
 'exit', 'flags', 'float_info', 'getcheckinterval',
 'getdefaultencoding', 'getfil
esystemencoding', 'getprofile', 'getrecursionlimit', 'getrefcount',
 'getsizeof',
 'gettrace', 'getwindowsversion', 'hexversion', 'intern', 'maxsize',
 'maxunicode
', 'meta_path', 'modules', 'path', 'path_hooks', 'path_importer_cache',
```

```
'platform', 'prefix', 'ps1', 'ps2', 'setcheckinterval', 'setprofile',
'setrecursionlimit', 'settrace', 'stderr', 'stdin', 'stdout', 'subversion', 'version',
'version_in', 'warnoptions', 'winver']

>>> dir() # get list of attributes for current module
['__builtins__', '__doc__', '__name__', '__package__', 'sys']

>>> a = 5 # create a new variable 'a'

>>> dir()
['__builtins__', '__doc__', '__name__', '__package__', 'a', 'sys']

>>> del a # delete/remove a name

>>> dir()
['__builtins__', '__doc__', '__name__', '__package__', 'sys']

>>>
```

How It Works:

First, we see the usage of `dir` on the imported `sys` module. We can see the huge list of attributes that it contains.

Next, we use the `dir` function without passing parameters to it. By default, it returns the list of attributes for the current module. Notice that the list of imported modules is also part of this list.

In order to observe the `dir` in action, we define a new variable `a` and assign it a value and then check `dir` and we observe that there is an additional value in the list of the same name. We remove the variable/attribute of the current module using the `del` statement and the change is reflected again in the output of the `dir` function.

A note on `del` - this statement is used to *delete* a variable/name and after the statement has run, in this case `del a`, you can no longer access the variable `a` - it is as if it never existed before at all.

Note that the `dir()` function works on *any* object. For example, run `dir(print)` to learn about the attributes of the `print` function, or `dir(str)` for the attributes of the `str` class.

Packages

By now, you must have started observing the hierarchy of organizing your programs. Variables usually go inside functions. Functions and global variables usually go inside modules. What if you wanted to organize modules? That's where packages come into the picture.

Packages are just folders of modules with a special `__init__.py` file that indicates to Python that this folder is special because it contains Python modules.

Let's say you want to create a package called 'world' with subpackages 'asia', 'africa', etc. and these subpackages in turn contain modules like 'india', 'madagascar', etc.

This is how you would structure the folders:

```
- <some folder present in the sys.path>/
  - world/
    - __init__.py
    - asia/
      - __init__.py
      - india/
        - __init__.py
        - foo.py
    - africa/
      - __init__.py
      - madagascar/
        - __init__.py
        - bar.py
```

Packages are just a convenience to hierarchically organize modules. You will see many instances of this in the standard library.

Summary

Just like functions are reusable parts of programs, modules are reusable programs. Packages are another hierarchy to organize modules. The standard library that comes with Python is an example of such a set of packages and modules.

We have seen how to use these modules and create our own modules.

Next, we will learn about some interesting concepts called data structures.

Python en:Data Structures

Introduction

Data structures are basically just that - they are *structures* which can hold some *data* together. In other words, they are used to store a collection of related data.

There are **four built-in data structures in Python - list, tuple, dictionary and set**. We will see how to use each of them and how they make life easier for us.

List

A list is a data structure that holds an ordered collection of items i.e. you can store a *sequence* of items in a list. This is easy to imagine if you can think of a shopping list where you have a list of items to buy, except that you probably have each item on a separate line in your shopping list whereas in Python you put commas in between them.

The list of items should be enclosed in square brackets so that Python understands that you are specifying a list. Once you have created a list, you can add, remove or search for items in the list. Since we can add and remove items, we say that a list is a *mutable* data type i.e. this type can be altered.

Quick Introduction To Objects And Classes

Although I've been generally delaying the discussion of objects and classes till now, a little explanation is needed right now so that you can understand lists better. We will explore this topic in detail later in its own chapter.

A list is an example of usage of objects and classes. When we use a variable *i* and assign a value to it, say integer 5 to it, you can think of it as creating an **object** (i.e. instance) *i* of **class** (i.e. type) `int`. In fact, you can read `help(int)` to understand this better.

A class can also have **methods** i.e. functions defined for use with respect to that class only. You can use these pieces of functionality only when you have an object of that class. For example, Python provides **an append method for the list class which allows you to add an item to the end of the list**. For example, `mylist.append('an item')` will add that string to the list `mylist`. Note the use of dotted notation for accessing methods of the objects.

A class can also have **fields** which are nothing but variables defined for use with respect to that class only. You can use these variables/names only when you have an object of that class. Fields are also accessed by the dotted notation, for example, `mylist.field`.

Example:

```
#!/usr/bin/python
# Filename: using_list.py

# This is my shopping list
shoplist = ['apple', 'mango', 'carrot', 'banana']

print('I have', len(shoplist), 'items to purchase.')

print('These items are:', end=' ')
```

```
for item in shoplist:
    print(item, end=' ')

print('\nI also have to buy rice.')
shoplist.append('rice')
print('My shopping list is now', shoplist)

print('I will sort my list now')
shoplist.sort()
print('Sorted shopping list is', shoplist)

print('The first item I will buy is', shoplist[0])
olditem = shoplist[0]
del shoplist[0]
print('I bought the', olditem)
print('My shopping list is now', shoplist)
```

Output:

```
$ python using_list.py
I have 4 items to purchase.
These items are: apple mango carrot banana
I also have to buy rice.
My shopping list is now ['apple', 'mango', 'carrot', 'banana',
'rice']
I will sort my list now
Sorted shopping list is ['apple', 'banana', 'carrot', 'mango',
'rice']
The first item I will buy is apple
I bought the apple
My shopping list is now ['banana', 'carrot', 'mango', 'rice']
```

How It Works:

The variable `shoplist` is a shopping list for someone who is going to the market. In `shoplist`, we only store strings of the names of the items to buy but you can add *any kind of object* to a list including numbers and even other lists.

We have also used the `for..in` loop to iterate through the items of the list. By now, you must have realised that a list is also a sequence. The speciality of sequences will be discussed in a later section.

Notice the use of the `end` keyword argument to the `print` function to indicate that we want to end the output with a space instead of the usual line break.

Next, we add an item to the list using the `append method` of the list object, as already discussed before. Then, we check that the item has been indeed added to the list by printing the contents of the list by simply passing the list to the `print` statement which prints it neatly.

Then, we sort the list by using the `sort method` of the list. It is important to understand that this method affects the list itself and does not return a modified list - this is different from the way strings work. This is what we mean by saying that `lists are mutable` and that

strings are *immutable*.

Next, when we finish buying an item in the market, we want to remove it from the list. We achieve this by using the **del statement**. Here, we mention which item of the list we want to remove and the del statement removes it from the list for us. We specify that we want to remove the first item from the list and hence we use `del shoplist[0]` (remember that Python starts counting from 0).

If you want to know all the methods defined by the list object, see `help(list)` for details.

Tuple

Tuples are used to hold together multiple objects. Think of them as similar to lists, but without the extensive functionality that the list class gives you. One major feature of tuples is that they are **immutable** like strings i.e. you cannot modify tuples.

Tuples are defined by specifying items separated by commas within an optional pair of parentheses.

Tuples are usually used in cases where a statement or a user-defined function can safely assume that the collection of values i.e. the tuple of values used will not change.

Example:

```
#!/usr/bin/python
# Filename: using_tuple.py

zoo = ('python', 'elephant', 'penguin') # remember the parentheses are
optional
print('Number of animals in the zoo is', len(zoo))

new_zoo = ('monkey', 'camel', zoo)
print('Number of cages in the new zoo is', len(new_zoo))
print('All animals in new zoo are', new_zoo)
print('Animals brought from old zoo are', new_zoo[2])
print('Last animal brought from old zoo is', new_zoo[2][2])
print('Number of animals in the new zoo is',
len(new_zoo)-1+len(new_zoo[2]))
```

Output:

```
$ python using_tuple.py
Number of animals in the zoo is 3
Number of cages in the new zoo is 3
All animals in new zoo are ('monkey', 'camel', ('python',
'elephant', 'penguin'))
Animals brought from old zoo are ('python', 'elephant', 'penguin')
Last animal brought from old zoo is penguin
Number of animals in the new zoo is 5
```

How It Works:

The variable `zoo` refers to a tuple of items. We see that the `len` function can be used to get the length of the tuple. This also indicates that a tuple is a sequence as well.

We are now shifting these animals to a new zoo since the old zoo is being closed. Therefore, the `new_zoo` tuple contains some animals which are already there along with the animals brought over from the old zoo. Back to reality, note that a tuple within a tuple does not lose its identity.

We can access the items in the tuple by specifying the item's position within a pair of square brackets just like we did for lists. This is called the *indexing* operator. We access the third item in `new_zoo` by specifying `new_zoo[2]` and we access the third item within the third item in the `new_zoo` tuple by specifying `new_zoo[2][2]`. This is pretty simple once you've understood the idiom.

Parentheses

Although the parentheses is optional, I prefer always having them to make it obvious that it is a tuple, especially because it avoids ambiguity. For example, `print(1,2,3)` and `print((1,2,3))` mean two different things - the former prints three numbers whereas the latter prints a tuple (which contains three numbers).

Tuple with 0 or 1 items

An **empty tuple** is constructed by an empty pair of parentheses such as `myempty = ()`. However, a tuple with a single item is not so simple. You have to specify it using a comma following the first (and only) item so that Python can differentiate between a tuple and a pair of parentheses surrounding the object in an expression i.e. you have to specify `singleton = (2 ,)` if you mean you want a tuple containing the item 2.

Note for Perl programmers

A list within a list does not lose its identity i.e. lists are not flattened as in Perl. The same applies to a tuple within a tuple, or a tuple within a list, or a list within a tuple, etc. As far as Python is concerned, they are just objects stored using another object, that's all.

Dictionary

A dictionary is like an address-book where you can find the address or contact details of a person by knowing only his/her name i.e. **we associate keys (name) with values (details)**. Note that the key must be unique just like you cannot find out the correct information if you have two persons with the exact same name.

Note that you can **use only immutable objects (like strings) for the keys** of a dictionary but you can **use either immutable or mutable objects for the values** of the dictionary. This basically translates to say that you should use only simple objects for keys.

Pairs of keys and values are specified in a dictionary by using the notation `d = {key1 : value1, key2 : value2 }`. Notice that the key-value pairs are separated by a colon and the pairs are separated themselves by commas and all this is enclosed in a pair of curly braces.

Remember that key-value pairs in a dictionary are not ordered in any manner. If you want a particular order, then you will have to sort them yourself before using it.

The dictionaries that you will be using are instances/objects of the `dict` class.

Example:

```
#!/usr/bin/python
# Filename: using_dict.py
```

```
# 'ab' is short for 'a'ddress'b'ook

ab = { 'Swaroop'   : 'swaroop@swaroopch.com',
       'Larry'    : 'larry@wall.org',
       'Matsumoto' : 'matz@ruby-lang.org',
       'Spammer'   : 'spammer@hotmail.com'
     }

print("Swaroop's address is", ab['Swaroop'])

# Deleting a key-value pair
del ab['Spammer']

print('\nThere are {0} contacts in the address-book\n'.format(len(ab)))

for name, address in ab.items():
    print('Contact {0} at {1}'.format(name, address))

# Adding a key-value pair
ab['Guido'] = 'guido@python.org'

if 'Guido' in ab: # OR ab.has_key('Guido')
    print("\nGuido's address is", ab['Guido'])
```

Output:

```
$ python using_dict.py
Swaroop's address is swaroop@swaroopch.com

There are 3 contacts in the address-book

Contact Swaroop at swaroop@swaroopch.com
Contact Matsumoto at matz@ruby-lang.org
Contact Larry at larry@wall.org

Guido's address is guido@python.org
```

How It Works:

We create the dictionary `ab` using the notation already discussed. We then access key-value pairs by specifying the key using the indexing operator as discussed in the context of lists and tuples. Observe the simple syntax.

We can delete key-value pairs using our old friend - the `del` statement. We simply specify the dictionary and the indexing operator for the key to be removed and pass it to the `del` statement. There is no need to know the value corresponding to the key for this operation.

Next, we access each key-value pair of the dictionary using the `items` method of the dictionary which returns a list of tuples where each tuple contains a pair of items - the key followed by the value. We retrieve this pair and assign it to the variables `name` and `address` correspondingly for each pair using the `for..in` loop and then print these values in the

for-block.

We can add new key-value pairs by simply using the indexing operator to access a key and assign that value, as we have done for Guido in the above case.

We can check if a key-value pair exists using the `in` operator or even the `has_key` method of the `dict` class. You can see the documentation for the complete list of methods of the `dict` class using `help(dict)`.

Keyword Arguments and Dictionaries

On a different note, if you have used keyword arguments in your functions, you have already used dictionaries! Just think about it - the key-value pair is specified by you in the parameter list of the function definition and when you access variables within your function, it is just a key access of a dictionary (which is called the *symbol table* in compiler design terminology).

Sequences

Lists, tuples and strings are examples of sequences, but what are sequences and what is so special about them?

The major features is that they have membership tests (i.e. the `in` and `not in` expressions) and indexing operations. The indexing operation which allows us to fetch a particular item in the sequence directly.

The three types of sequences mentioned above - lists, tuples and strings, also have a slicing operation which allows us to retrieve a slice of the sequence i.e. a part of the sequence.

Example:

```
#!/usr/bin/python
# Filename: seq.py

shoplist = ['apple', 'mango', 'carrot', 'banana']
name = 'swaroop'

# Indexing or 'Subscription' operation
print('Item 0 is', shoplist[0])
print('Item 1 is', shoplist[1])
print('Item 2 is', shoplist[2])
print('Item 3 is', shoplist[3])
print('Item -1 is', shoplist[-1])
print('Item -2 is', shoplist[-2])
print('Character 0 is', name[0])

# Slicing on a list
print('Item 1 to 3 is', shoplist[1:3])
print('Item 2 to end is', shoplist[2:])
print('Item 1 to -1 is', shoplist[1:-1])
print('Item start to end is', shoplist[:])

# Slicing on a string
```

```
print('characters 1 to 3 is', name[1:3])
print('characters 2 to end is', name[2:])
print('characters 1 to -1 is', name[1:-1])
print('characters start to end is', name[:])
```

Output:

```
$ python seq.py
Item 0 is apple
Item 1 is mango
Item 2 is carrot
Item 3 is banana
Item -1 is banana
Item -2 is carrot
Character 0 is s
Item 1 to 3 is ['mango', 'carrot']
Item 2 to end is ['carrot', 'banana']
Item 1 to -1 is ['mango', 'carrot']
Item start to end is ['apple', 'mango', 'carrot', 'banana']
characters 1 to 3 is wa
characters 2 to end is aroop
characters 1 to -1 is waroo
characters start to end is swaroop
```

How It Works:

First, we see how to use indexes to get individual items of a sequence. This is also referred to as the *subscription operation*. Whenever you specify a number to a sequence within square brackets as shown above, Python will fetch you the item corresponding to that position in the sequence. Remember that Python starts counting numbers from 0. Hence, `shoplist[0]` fetches the first item and `shoplist[3]` fetches the fourth item in the `shoplist` sequence.

The index can also be a negative number, in which case, the position is calculated from the end of the sequence. Therefore, `shoplist[-1]` refers to the last item in the sequence and `shoplist[-2]` fetches the second last item in the sequence.

The slicing operation is used by specifying the name of the sequence followed by an optional pair of numbers separated by a colon within square brackets. Note that this is very similar to the indexing operation you have been using till now. Remember the numbers are optional but the colon isn't.

The first number (before the colon) in the slicing operation refers to the position from where the slice starts and the second number (after the colon) indicates where the slice will stop at. If the first number is not specified, Python will start at the beginning of the sequence. If the second number is left out, Python will stop at the end of the sequence. Note that the slice returned **starts** at the start position and will end just before the **end** position i.e. the start position is included but the end position is excluded from the sequence slice.

Thus, `shoplist[1:3]` returns a slice of the sequence starting at position 1, includes position 2 but stops at position 3 and therefore a *slice* of two items is returned. Similarly, `shoplist[:]` returns a copy of the whole sequence.

You can also do slicing with negative positions. Negative numbers are used for positions from the end of the sequence. For example, `shoplist[:-1]` will return a slice of the sequence which excludes the last item of the sequence but contains everything else.

You can also provide a third argument for the slice, which is the **step for the slicing** (by default, the step size is 1):

```
>>> shoplist = ['apple', 'mango', 'carrot', 'banana']
>>> shoplist[::1]
['apple', 'mango', 'carrot', 'banana']
>>> shoplist[::2]
['apple', 'carrot']
>>> shoplist[::3]
['apple', 'banana']
>>> shoplist[::-1]
['banana', 'carrot', 'mango', 'apple']
```

Notice that when the step is 2, we get the items with position 0, 2, ... When the step size is 3, we get the items with position 0, 3, etc.

Try various combinations of such slice specifications using the Python interpreter interactively i.e. the prompt so that you can see the results immediately. **The great thing about sequences is that you can access tuples, lists and strings all in the same way!**

Set

Sets are *unordered* collections of simple objects. These are used when the existence of an object in a collection is more important than the order or how many times it occurs.

Using sets, you can test for membership, whether it is a subset of another set, find the intersection between two sets, and so on.

```
>>> bri = set(['brazil', 'russia', 'india'])
>>> 'india' in bri
True
>>> 'usa' in bri
False
>>> bric = bri.copy()
>>> bric.add('china')
>>> bric.issuperset(bri)
True
>>> bri.remove('russia')
>>> bri & bric # OR bri.intersection(bric)
{'brazil', 'india'}
```

How It Works:

The example is pretty much self-explanatory because it involves basic set theory mathematics taught in school.

References

When you create an object and assign it to a variable, the variable only *refers* to the object and does not represent the object itself! That is, the variable name points to that part of your computer's memory where the object is stored. This is called as **binding** of the name to the object.

Generally, you don't need to be worried about this, but there is a subtle effect due to references which you need to be aware of:

Example:

```
#!/usr/bin/python
# Filename: reference.py

print('Simple Assignment')
shoplist = ['apple', 'mango', 'carrot', 'banana']
mylist = shoplist # mylist is just another name pointing to the same
object!

del shoplist[0] # I purchased the first item, so I remove it from the
list

print('shoplist is', shoplist)
print('mylist is', mylist)
# notice that both shoplist and mylist both print the same list without
# the 'apple' confirming that they point to the same object

print('Copy by making a full slice')
mylist = shoplist[:] # make a copy by doing a full slice
del mylist[0] # remove first item

print('shoplist is', shoplist)
print('mylist is', mylist)
# notice that now the two lists are different
```

Output:

```
$ python reference.py
Simple Assignment
shoplist is ['mango', 'carrot', 'banana']
mylist is ['mango', 'carrot', 'banana']
Copy by making a full slice
shoplist is ['mango', 'carrot', 'banana']
mylist is ['carrot', 'banana']
```

How It Works:

Most of the explanation is available in the comments.

Remember that if you want to make a copy of a list or such kinds of sequences or complex objects (not simple *objects* such as integers), then you have to use the slicing operation to make a copy. If you just assign the variable name to another name, both of them will *refer*

to the same object and this could be trouble if you are not careful.

Note for Perl programmers

Remember that an assignment statement for lists does **not** create a copy. You have to use slicing operation to make a copy of the sequence.

More About Strings

We have already discussed strings in detail earlier. What more can there be to know? Well, did you know that strings are also objects and have methods which do everything from checking part of a string to stripping spaces!

The strings that you use in program are all objects of the class `str`. Some useful methods of this class are demonstrated in the next example. For a complete list of such methods, see `help(str)`.

Example:

```
#!/usr/bin/python
# Filename: str_methods.py

name = 'Swaroop' # This is a string object

if name.startswith('Swa'):
    print('Yes, the string starts with "Swa"')

if 'a' in name:
    print('Yes, it contains the string "a"')

if name.find('war') != -1:
    print('Yes, it contains the string "war"')

delimiter = '_*_*'
mylist = ['Brazil', 'Russia', 'India', 'China']
print(delimiter.join(mylist))
```

Output:

```
$ python str_methods.py
Yes, the string starts with "Swa"
Yes, it contains the string "a"
Yes, it contains the string "war"
Brazil_*_Russia_*_India_*_China
```

How It Works:

Here, we see a lot of the string methods in action. The `startswith` method is used to find out whether the string starts with the given string. The `in` operator is used to check if a given string is a part of the string.

The `find` method is used to do find the position of the given string in the string or returns -1 if it is not successful to find the substring. The `str` class also has a neat method to join the items of a sequence with the string acting as a delimiter between each item of the sequence and returns a bigger string generated from this.

Summary

We have explored the various built-in data structures of Python in detail. These data structures will be essential for writing programs of reasonable size.

Now that we have a lot of the basics of Python in place, we will next see how to design and write a real-world Python program.

Python en:Problem Solving

We have explored various parts of the Python language and now we will take a look at how all these parts fit together, by designing and writing a program which *does* something useful. The idea is to learn how to write a Python script on your own.

The Problem

The problem is *"I want a program which creates a backup of all my important files"*.

Although, this is a simple problem, there is not enough information for us to get started with the solution. A little more **analysis** is required. For example, how do we specify *which* files are to be backed up? *How* are they stored? *Where* are they stored?

After analyzing the problem properly, we **design** our program. We make a list of things about how our program should work. In this case, I have created the following list on how *I* want it to work. If you do the design, you may not come up with the same kind of analysis since every person has their own way of doing things, so that is perfectly okay.

1. The files and directories to be backed up are specified in a list.
 2. The backup must be stored in a main backup directory.
 3. The files are backed up into a zip file.
 4. The name of the zip archive is the current date and time.
 5. We use the standard zip command available by default in any standard Linux/Unix distribution. Windows users can install (<http://gnuwin32.sourceforge.net/downloads/zip.php>) from the **GnuWin32 project** page (<http://gnuwin32.sourceforge.net/packages/zip.htm>) and add C:\Program Files\GnuWin32\bin to your system PATH environment variable, similar to what we did for recognizing the python command itself. Note that you can use any archiving command you want as long as it has a command line interface so that we can pass arguments to it from our script.
-

The Solution

As the design of our program is now reasonably stable, we can write the code which is an **implementation** of our solution.

```
#!/usr/bin/python
# Filename: backup_ver1.py

import os
import time

# 1. The files and directories to be backed up are specified in a list.
source = ['C:\\My Documents', 'C:\\Code']
# Notice we had to use double quotes inside the string for names with
spaces in it.

# 2. The backup must be stored in a main backup directory
target_dir = 'E:\\Backup' # Remember to change this to what you will be
    using

# 3. The files are backed up into a zip file.
# 4. The name of the zip archive is the current date and time
target = target_dir + os.sep + time.strftime('%Y%m%d%H%M%S') + '.zip'

# 5. We use the zip command to put the files in a zip archive
zip_command = "zip -qr {0} {1}".format(target, ' '.join(source))

# Run the backup
if os.system(zip_command) == 0:
    print('Successful backup to', target)
else:
    print('Backup FAILED')
```

Output:

```
$ python backup_ver1.py
Successful backup to E:\Backup\20080702185040.zip
```

Now, we are in the **testing** phase where we test that our program works properly. If it doesn't behave as expected, then we have to **debug** our program i.e. remove the *bugs* (errors) from the program.

If the above program does not work for you, put a `print(zip_command)` just before the `os.system` call and run the program. Now copy/paste the printed `zip_command` to the shell prompt and see if it runs properly on its own. If this command fails, check the zip command manual on what could be wrong. If this command succeeds, then check the Python program if it exactly matches the program written above.

How It Works:

You will notice how we have converted our *design* into *code* in a step-by-step manner.

We make use of the `os` and `time` modules by first importing them. Then, we specify the files and directories to be backed up in the `source` list. The target directory is where store all the backup files and this is specified in the `target_dir` variable. The name of the zip archive that we are going to create is the current date and time which we find out using the `time.strftime()` function. It will also have the `.zip` extension and will be stored in the `target_dir` directory.

Notice the use of `os.sep` variable - this gives the directory separator according to your operating system i.e. it will be `'/'` in Linux, Unix, it will be `'\\'` in Windows and `':'` in Mac OS. Using `os.sep` instead of these characters directly will make our program portable and work across these systems.

The `time.strftime()` function takes a specification such as the one we have used in the above program. The `%Y` specification will be replaced by the year without the century. The `%m` specification will be replaced by the month as a decimal number between 01 and 12 and so on. The complete list of such specifications can be found in the Python Reference Manual (<http://docs.python.org/dev/3.0/library/time.html#time.strftime>).

We create the name of the target zip file using the addition operator which *concatenates* the strings i.e. it joins the two strings together and returns a new one. Then, we create a string `zip_command` which contains the command that we are going to execute. You can check if this command works by running it on the shell (Linux terminal or DOS prompt).

The `zip` command that we are using has some options and parameters passed. The `-q` option is used to indicate that the `zip` command should work **quietly**. The `-r` option specifies that the `zip` command should work **recursively** for directories i.e. it should include all the subdirectories and files. The two options are combined and specified in a shortcut as `-qr`. The options are followed by the name of the zip archive to create followed by the list of files and directories to backup. We convert the `source` list into a string using the `join` method of strings which we have already seen how to use.

Then, we finally *run* the command using the `os.system` function which runs the command as if it was run from the *system* i.e. in the shell - it returns 0 if the command was successfully, else it returns an error number.

Depending on the outcome of the command, we print the appropriate message that the backup has failed or succeeded.

That's it, we have created a script to take a backup of our important files!

Note to Windows Users

Instead of double backslash escape sequences, you can also use raw strings. For example, use `'C:\\Documents'` or `r'C:\Documents'`. However, do **not** use `'C:\Documents'` since you end up using an unknown escape sequence `\D`.

Now that we have a working backup script, we can use it whenever we want to take a backup of the files. Linux/Unix users are advised to use the executable method as discussed earlier so that they can run the backup script anytime anywhere. This is called the **operation** phase or the **deployment** phase of the software.

The above program works properly, but (usually) first programs do not work exactly as you expect. For example, there might be problems if you have not designed the program properly or if you have made a mistake in typing the code, etc. Appropriately, you will have to go back to the design phase or you will have to debug your program.

Second Version

The first version of our script works. However, we can make some refinements to it so that it can work better on a daily basis. This is called the **maintenance** phase of the software.

One of the refinements I felt was useful is a better file-naming mechanism - using the *time* as the name of the file within a directory with the current *date* as a directory within the main backup directory. First advantage is that your backups are stored in a hierarchical manner and therefore it is much easier to manage. Second advantage is that the length of the filenames are much shorter. Third advantage is that separate directories will help you to easily check if you have taken a backup for each day since the directory would be created only if you have taken a backup for that day.

```
#!/usr/bin/python
# Filename: backup_ver2.py

import os
import time

# 1. The files and directories to be backed up are specified in a list.
source = ['C:\\My Documents', 'C:\\Code']
# Notice we had to use double quotes inside the string for names with
spaces in it.

# 2. The backup must be stored in a main backup directory
target_dir = 'E:\\Backup' # Remember to change this to what you will be
    using

# 3. The files are backed up into a zip file.
# 4. The current day is the name of the subdirectory in the main
    directory
today = target_dir + os.sep + time.strftime('%Y%m%d')
# The current time is the name of the zip archive
now = time.strftime('%H%M%S')

# Create the subdirectory if it isn't already there
if not os.path.exists(today):
    os.mkdir(today) # make directory
    print('Successfully created directory', today)

# The name of the zip file
target = today + os.sep + now + '.zip'

# 5. We use the zip command to put the files in a zip archive
zip_command = "zip -qr {0} {1}".format(target, ' '.join(source))

# Run the backup
if os.system(zip_command) == 0:
    print('Successful backup to', target)
```

```
else:
    print('Backup FAILED')
```

Output:

```
$ python backup_ver2.py
Successfully created directory E:\Backup\20080702
Successful backup to E:\Backup\20080702\202311.zip

$ python backup_ver2.py
Successful backup to E:\Backup\20080702\202325.zip
```

How It Works:

Most of the program remains the same. The changes is that we check if there is a directory with the current day as name inside the main backup directory using the `os.path.exists` function. If it doesn't exist, we create it using the `os.mkdir` function.

Third Version

The second version works fine when I do many backups, but when there are lots of backups, I am finding it hard to differentiate what the backups were for! For example, I might have made some major changes to a program or presentation, then I want to associate what those changes are with the name of the zip archive. This can be easily achieved by attaching a user-supplied comment to the name of the zip archive.

Note

The following program does not work, so do not be alarmed, please follow along because there's a lesson in here.

```
#!/usr/bin/python
# Filename: backup_ver3.py

import os
import time

# 1. The files and directories to be backed up are specified in a list.
source = ['C:\\My Documents', 'C:\\Code']
# Notice we had to use double quotes inside the string for names with
spaces in it.

# 2. The backup must be stored in a main backup directory
target_dir = 'E:\\Backup' # Remember to change this to what you will be
using

# 3. The files are backed up into a zip file.
# 4. The current day is the name of the subdirectory in the main
directory
today = target_dir + os.sep + time.strftime('%Y%m%d')
# The current time is the name of the zip archive
now = time.strftime('%H%M%S')
```

```

# Take a comment from the user to create the name of the zip file
comment = input('Enter a comment --> ')
if len(comment) == 0: # check if a comment was entered
    target = today + os.sep + now + '.zip'
else:
    target = today + os.sep + now + '_' +
        comment.replace(' ', '_') + '.zip'

# Create the subdirectory if it isn't already there
if not os.path.exists(today):
    os.mkdir(today) # make directory
    print('Successfully created directory', today)

# 5. We use the zip command to put the files in a zip archive
zip_command = "zip -qr {0} {1}".format(target, ' '.join(source))

# Run the backup
if os.system(zip_command) == 0:
    print('Successful backup to', target)
else:
    print('Backup FAILED')

```

Output:

```

$ python backup_ver3.py
File "backup_ver3.py", line 25
    target = today + os.sep + now + '_' +
                                         ^
SyntaxError: invalid syntax

```

How This (does not) Work:

This program does not work! Python says there is a syntax error which means that the script does not satisfy the structure that Python expects to see. When we observe the error given by Python, it also tells us the place where it detected the error as well. So we start *debugging* our program from that line.

On careful observation, we see that the single logical line has been split into two physical lines but we have not specified that these two physical lines belong together. Basically, Python has found the addition operator (+) without any operand in that logical line and hence it doesn't know how to continue. Remember that we can specify that the logical line continues in the next physical line by the use of a backslash at the end of the physical line. So, we make this correction to our program. This correction of the program when we find errors is called **bug fixing**.

Fourth Version

```
#!/usr/bin/python
# Filename: backup_ver4.py

import os
import time

# 1. The files and directories to be backed up are specified in a list.
source = ['C:\\My Documents', 'C:\\Code']
# Notice we had to use double quotes inside the string for names with
spaces in it.

# 2. The backup must be stored in a main backup directory
target_dir = 'E:\\Backup' # Remember to change this to what you will be
    using

# 3. The files are backed up into a zip file.
# 4. The current day is the name of the subdirectory in the main
    directory
today = target_dir + os.sep + time.strftime('%Y%m%d')
# The current time is the name of the zip archive
now = time.strftime('%H%M%S')

# Take a comment from the user to create the name of the zip file
comment = input('Enter a comment --> ')
if len(comment) == 0: # check if a comment was entered
    target = today + os.sep + now + '.zip'
else:
    target = today + os.sep + now + '_' + \
        comment.replace(' ', '_') + '.zip'

# Create the subdirectory if it isn't already there
if not os.path.exists(today):
    os.mkdir(today) # make directory
    print('Successfully created directory', today)

# 5. We use the zip command to put the files in a zip archive
zip_command = "zip -qr {0} {1}".format(target, ' '.join(source))

# Run the backup
if os.system(zip_command) == 0:
    print('Successful backup to', target)
else:
    print('Backup FAILED')
```

Output:

```
$ python backup_ver4.py
Enter a comment --> added new examples
Successful backup to
E:\Backup\20080702\202836_added_new_examples.zip

$ python backup_ver4.py
Enter a comment -->
Successful backup to E:\Backup\20080702\202839.zip
```

How It Works:

This program now works! Let us go through the actual enhancements that we had made in version 3. We take in the user's comments using the `input` function and then check if the user actually entered something by finding out the length of the input using the `len` function. If the user has just pressed enter without entering anything (maybe it was just a routine backup or no special changes were made), then we proceed as we have done before.

However, if a comment was supplied, then this is attached to the name of the zip archive just before the `.zip` extension. Notice that we are replacing spaces in the comment with underscores - this is because managing filenames without spaces are much easier.

More Refinements

The fourth version is a satisfactorily working script for most users, but there is always room for improvement. For example, you can include a *verbosity* level for the program where you can specify a `-v` option to make your program become more talkative.

Another possible enhancement would be to allow extra files and directories to be passed to the script at the command line. We can get these names from the `sys.argv` list and we can add them to our source list using the `extend` method provided by the `list` class.

The most important refinement would be to not use the `os.system` way of creating archives and instead using the `zipfile` or `tarfile` built-in module to create these archives. They are part of the standard library and available already for you to use without external dependencies on the zip program to be available on your computer.

However, I have been using the `os.system` way of creating a backup in the above examples purely for pedagogical purposes, so that the example is simple enough to be understood by everybody but real enough to be useful.

Can you try writing the fifth version that `uses the zipfile` (<http://docs.python.org/dev/3.0/library/zipfile.html>) module instead of the `os.system` call?

The Software Development Process

We have now gone through the various **phases** in the process of writing a software. These phases can be summarised as follows:

1. What (Analysis)
2. How (Design)
3. Do It (Implementation)
4. Test (Testing and Debugging)
5. Use (Operation or Deployment)
6. Maintain (Refinement)

A recommended way of writing programs is the procedure we have followed in creating the backup script: Do the analysis and design. Start implementing with a simple version. Test and debug it. Use it to ensure that it works as expected. Now, add any features that you want and continue to repeat the Do It-Test-Use cycle as many times as required. Remember, **Software is grown, not built**.

Summary

We have seen how to create our own Python programs/scripts and the various stages involved in writing such programs. You may find it useful to create your own program just like we did in this chapter so that you become comfortable with Python as well as problem-solving.

Next, we will discuss object-oriented programming.

Python en:Object Oriented Programming

Introduction

In all the programs we wrote till now, we have designed our program around functions i.e. blocks of statements which manipulate data. This is called the *procedure-oriented* way of programming. There is another way of organizing your program which is to combine data and functionality and wrap it inside something called an object. This is called the *object oriented* programming paradigm. Most of the time you can use procedural programming, but when writing large programs or have a problem that is better suited to this method, you can use object oriented programming techniques.

Classes and objects are the two main aspects of object oriented programming. A **class** creates a new *type* where **objects** are *instances* of the class. An analogy is that you can have variables of type `int` which translates to saying that variables that store integers are variables which are instances (objects) of the `int` class.

Note for Static Language Programmers

Note that even integers are treated as objects (of the `int` class). This is unlike C++ and Java (before version 1.5) where integers are primitive native types. See `help(int)` for more details on the class.

C# and Java 1.5 programmers will find this similar to the *boxing and unboxing* concept.

Objects can store data using ordinary variables that *belong* to the object. Variables that belong to an object or class are referred to as **fields**. Objects can also have functionality by using functions that *belong* to a class. Such functions are called **methods** of the class. This terminology is important because it helps us to differentiate between functions and variables which are independent and those which belong to a class or object. Collectively, the fields and methods can be referred to as the **attributes** of that class.

Fields are of two types - they can belong to each instance/object of the class or they can belong to the class itself. They are called **instance variables** and **class variables** respectively.

A class is created using the `class` keyword. The fields and methods of the class are listed in an indented block.

The self

Class methods have only one specific difference from ordinary functions - they must have an extra first name that has to be added to the beginning of the parameter list, but you **do not** give a value for this parameter when you call the method, Python will provide it. This particular variable refers to the object *itself*, and by convention, it is given the name `self`.

Although, you can give any name for this parameter, it is *strongly recommended* that you use the name `self` - any other name is definitely frowned upon. There are many advantages to using a standard name - any reader of your program will immediately recognize it and even specialized IDEs (Integrated Development Environments) can help you if you use `self`.

Note for C++/Java/C# Programmers

The `self` in Python is equivalent to the `this` pointer in C++ and the `this` reference in Java and C#.

You must be wondering how Python gives the value for `self` and why you don't need to give a value for it. An example will make this clear. Say you have a class called `MyClass` and an instance of this class called `myobject`. When you call a method of this object as `myobject.method(arg1, arg2)`, this is automatically converted by Python into `MyClass.method(myobject, arg1, arg2)` - this is all the special `self` is about.

This also means that if you have a method which takes no arguments, then you still have to have one argument - the `self`.

Classes

The simplest class possible is shown in the following example.

```
#!/usr/bin/python
# Filename: simplestclass.py

class Person:
    pass # An empty block

p = Person()
print(p)
```

Output:

```
$ python simplestclass.py
<__main__.Person object at 0x019F85F0>
```

How It Works:

We create a new class using the `class` statement and the name of the class. This is followed by an indented block of statements which form the body of the class. In this case, we have an empty block which is indicated using the `pass` statement.

Next, we create an object/instance of this class using the name of the class followed by a pair of parentheses. (We will learn more about instantiation in the next section). For our verification, we confirm the type of the variable by simply printing it. It tells us that we have an instance of the `Person` class in the `__main__` module.

Notice that the address of the computer memory where your object is stored is also printed. The address will have a different value on your computer since Python can store the object wherever it finds space.

Object Methods

We have already discussed that classes/objects can have methods just like functions except that we have an extra `self` variable. We will now see an example.

```
#!/usr/bin/python
# Filename: method.py

class Person:
    def sayHi(self):
        print('Hello, how are you?')

p = Person()
p.sayHi()

# This short example can also be written as Person().sayHi()
```

Output:

```
$ python method.py
Hello, how are you?
```

How It Works:

Here we see the `self` in action. Notice that the `sayHi` method takes no parameters but still has the `self` in the function definition.

The `__init__` method

There are many method names which have special significance in Python classes. We will see the significance of the `__init__` method now.

The `__init__` method is run as soon as an object of a class is instantiated. The method is useful to do any **initialization** you want to do with your object. Notice the double underscores both at the beginning and at the end of the name.

Example:

```
#!/usr/bin/python
# Filename: class_init.py

class Person:
    def __init__(self, name):
        self.name = name
    def sayHi(self):
        print('Hello, my name is', self.name)

p = Person('Swaroop')
p.sayHi()

# This short example can also be written as Person('Swaroop').sayHi()
```

Output:

```
$ python class_init.py
Hello, my name is Swaroop
```

How It Works:

Here, we define the `__init__` method as taking a parameter name (along with the usual `self`). Here, we just create a new field also called `name`. Notice these are two different variables even though they are both called 'name'. The dotted notation allows us to differentiate between them.

Most importantly, notice that we do not explicitly call the `__init__` method but pass the arguments in the parentheses following the class name when creating a new instance of the class. This is the special significance of this method.

Now, we are able to use the `self.name` field in our methods which is demonstrated in the `sayHi` method.

Class And Object Variables

We have already discussed the functionality part of classes and objects (i.e. methods), now let us learn about the data part. The data part, i.e. fields, are nothing but ordinary variables that are *bound* to the **namespaces** of the classes and objects. This means that these names are valid within the context of these classes and objects only. That's why they are called *name spaces*.

There are two types of *fields* - class variables and object variables which are classified depending on whether the class or the object owns the variables respectively.

Class variables are shared - they can be accessed by all instances of that class. There is only one copy of the class variable and when any one object makes a change to a class variable, that change will be seen by all the other instances.

Object variables are owned by each individual object/instance of the class. In this case, each object has its own copy of the field i.e. they are not shared and are not related in any way to the field by the same name in a different instance. An example will make this easy to understand:

```
#!/usr/bin/python
# Filename: objvar.py

class Robot:
    '''Represents a robot, with a name.'''

    # A class variable, counting the number of robots
    population = 0

    def __init__(self, name):
        '''Initializes the data.'''
        self.name = name
        print('(Initializing {0})'.format(self.name))

        # When this person is created, the robot
        # adds to the population
        Robot.population += 1
```

```

def __del__(self):
    '''I am dying.'''
    print('{0} is being destroyed!'.format(self.name))

    Robot.population -= 1

    if Robot.population == 0:
        print('{0} was the last one.'.format(self.name))
    else:
        print('There are still {0:d} robots
working.'.format(Robot.population))

def sayHi(self):
    '''Greeting by the robot.

    Yeah, they can do that.'''
    print('Greetings, my masters call me {0}.'.format(self.name))

def howMany():
    '''Prints the current population.'''
    print('We have {0:d} robots.'.format(Robot.population))
    howMany = staticmethod(howMany)

droid1 = Robot('R2-D2')
droid1.sayHi()
Robot.howMany()

droid2 = Robot('C-3P0')
droid2.sayHi()
Robot.howMany()

print("\nRobots can do some work here.\n")

print("Robots have finished their work. So let's destroy them.")
del droid1
del droid2

Robot.howMany()

```

Output:

```

(Initializing R2-D2)
Greetings, my masters call me R2-D2.
We have 1 robots.
(Initializing C-3P0)
Greetings, my masters call me C-3P0.
We have 2 robots.

```

Robots can do some work here.

Robots have finished their work. So let's destroy them.

R2-D2 is being destroyed!

There are still 1 robots working.

C-3P0 is being destroyed!

C-3P0 was the last one.

We have 0 robots.

How It Works:

This is a long example but helps demonstrate the nature of class and object variables. Here, `population` belongs to the `Robot` class and hence is a class variable. The `name` variable belongs to the object (it is assigned using `self`) and hence is an object variable.

Thus, we refer to the `population` class variable as `Robot.population` and not as `self.population`. We refer to the object variable name using `self.name` notation in the methods of that object. Remember this simple difference between class and object variables. Also note that an object variable with the same name as a class variable will hide the class variable!

The `howMany` is actually a method that belongs to the class and not to the object. This means we can define it as either a `classmethod` or a `staticmethod` depending on whether we need to know which class we are part of. Since we don't need such information, we will go for `staticmethod`.

We could have also achieved the same using decorators ([http:// www. ibm. com/ developerworks/linux/library/l-cpdecor.html](http://www.ibm.com/developerworks/linux/library/l-cpdecor.html)):

```
@staticmethod
def howMany():
    '''Prints the current population.'''
    print('We have {0:d} robots.'.format(Robot.population))
```

Decorators can be imagined to be a shortcut to calling an explicit statement, as we have seen in this example.

Observe that the `__init__` method is used to initialize the `Robot` instance with a name. In this method, we increase the `population` count by 1 since we have one more robot being added. Also observe that the values of `self.name` is specific to each object which indicates the nature of object variables.

Remember, that you must refer to the variables and methods of the same object using the `self` **only**. This is called an attribute reference.

In this program, we also see the use of **docstrings** for classes as well as methods. We can access the class docstring at runtime using `Robot.__doc__` and the method docstring as `Robot.sayHi.__doc__`

Just like the `__init__` method, there is another special method `__del__` which is called when an object is going to die i.e. it is no longer being used and is being returned to the computer system for reusing that piece of memory. In this method, we simply decrease the `Robot.population` count by 1.

The `__del__` method is run when the object is no longer in use and there is no guarantee when that method will be run. If you want to explicitly see it in action, we have to use the `del` statement which is what we have done here.

Note for C++/Java/C# Programmers

All class members (including the data members) are *public* and all the methods are *virtual* in Python.

One exception: If you use data members with names using the *double underscore* prefix such as `__privatevar`, Python uses name-mangling to effectively make it a private variable.

Thus, the convention followed is that any variable that is to be used only within the class or object should begin with an underscore and all other names are public and can be used by other classes/objects. Remember that this is only a convention and is not enforced by Python (except for the double underscore prefix).

Inheritance

One of the major benefits of object oriented programming is **reuse** of code and one of the ways this is achieved is through the *inheritance* mechanism. Inheritance can be best imagined as implementing a *type and subtype* relationship between classes.

Suppose you want to write a program which has to keep track of the teachers and students in a college. They have some common characteristics such as name, age and address. They also have specific characteristics such as salary, courses and leaves for teachers and, marks and fees for students.

You can create two independent classes for each type and process them but adding a new common characteristic would mean adding to both of these independent classes. This quickly becomes unwieldy.

A better way would be to create a common class called `SchoolMember` and then have the teacher and student classes *inherit* from this class i.e. they will become sub-types of this type (class) and then we can add specific characteristics to these sub-types.

There are many advantages to this approach. If we add/change any functionality in `SchoolMember`, this is automatically reflected in the subtypes as well. For example, you can add a new ID card field for both teachers and students by simply adding it to the `SchoolMember` class. However, changes in the subtypes do not affect other subtypes. Another advantage is that if you can refer to a teacher or student object as a `SchoolMember` object which could be useful in some situations such as counting of the number of school members. This is called **polymorphism** where a sub-type can be substituted in any situation where a parent type is expected i.e. the object can be treated as an instance of the parent class.

Also observe that we *reuse* the code of the parent class and we do not need to repeat it in the different classes as we would have had to in case we had used independent classes.

The `SchoolMember` class in this situation is known as the *base class* or the *superclass*. The Teacher and Student classes are called the *derived classes* or *subclasses*.

We will now see this example as a program.

```
#!/usr/bin/python
# Filename: inherit.py
```

```

class SchoolMember:
    '''Represents any school member.'''
    def __init__(self, name, age):
        self.name = name
        self.age = age
        print('(Initialized SchoolMember: {0})'.format(self.name))

    def tell(self):
        '''Tell my details.'''
        print('Name:"{0}" Age:"{1}"'.format(self.name, self.age), end="
")

class Teacher(SchoolMember):
    '''Represents a teacher.'''
    def __init__(self, name, age, salary):
        SchoolMember.__init__(self, name, age)
        self.salary = salary
        print('(Initialized Teacher: {0})'.format(self.name))

    def tell(self):
        SchoolMember.tell(self)
        print('Salary: "{0:d}"'.format(self.salary))

class Student(SchoolMember):
    '''Represents a student.'''
    def __init__(self, name, age, marks):
        SchoolMember.__init__(self, name, age)
        self.marks = marks
        print('(Initialized Student: {0})'.format(self.name))

    def tell(self):
        SchoolMember.tell(self)
        print('Marks: "{0:d}"'.format(self.marks))

t = Teacher('Mrs. Shrividya', 40, 30000)
s = Student('Swaroop', 25, 75)

print() # prints a blank line

members = [t, s]
for member in members:
    member.tell() # works for both Teachers and Students

```

Output:

```

$ python inherit.py
(Initialized SchoolMember: Mrs. Shrividya)

```

```
(Initialized Teacher: Mrs. Shrividya)
(Initialized SchoolMember: Swaroop)
(Initialized Student: Swaroop)

Name:"Mrs. Shrividya" Age:"40" Salary: "30000"
Name:"Swaroop" Age:"25" Marks: "75"
```

How It Works:

To use inheritance, we specify the base class names in a tuple following the class name in the class definition. Next, we observe that the `__init__` method of the base class is explicitly called using the `self` variable so that we can initialize the base class part of the object. This is very important to remember - Python does not automatically call the constructor of the base class, you have to explicitly call it yourself.

We also observe that we can call methods of the base class by prefixing the class name to the method call and then pass in the `self` variable along with any arguments.

Notice that we can treat instances of `Teacher` or `Student` as just instances of the `SchoolMember` when we use the `tell` method of the `SchoolMember` class.

Also, observe that the `tell` method of the subtype is called and not the `tell` method of the `SchoolMember` class. One way to understand this is that Python *always* starts looking for methods in the actual type, which in this case it does. If it could not find the method, it starts looking at the methods belonging to its base classes one by one in the order they are specified in the tuple in the class definition.

A note on terminology - if more than one class is listed in the inheritance tuple, then it is called multiple inheritance.

Summary

We have now explored the various aspects of classes and objects as well as the various terminologies associated with it. We have also seen the benefits and pitfalls of object-oriented programming. Python is highly object-oriented and understanding these concepts carefully will help you a lot in the long run.

Next, we will learn how to deal with input/output and how to access files in Python.

Python en:Input Output

Introduction

There will be situations where your program has to interact with the user. For example, you would want to take input from the user and then print some results back. We can achieve this using the `input()` and `print()` functions respectively.

For output, we can also use the various methods of the `str` (string) class. For example, you can use the `rjust` method to get a string which is right justified to a specified width. See `help(str)` for more details.

Another common type of input/output is dealing with files. The ability to create, read and write files is essential to many programs and we will explore this aspect in this chapter.

Input from user

```
#!/usr/bin/python
# user_input.py

def reverse(text):
    return text[::-1]

def is_palindrome(text):
    return text == reverse(text)

something = input('Enter text: ')
if (is_palindrome(something)):
    print("Yes, it is a palindrome")
else:
    print("No, it is not a palindrome")
```

Output:

```
$ python user_input.py
Enter text: sir
No, it is not a palindrome

$ python user_input.py
Enter text: madam
Yes, it is a palindrome

$ python user_input.py
Enter text: racecar
Yes, it is a palindrome
```

How It Works:

We use the slicing feature to reverse the text. We've already seen how we can make slices from sequences using the `seq[a:b]` code starting from position `a` to position `b`. We can also provide a third argument that determines the *step* by which the slicing is done. The

default step is 1 because of which it returns a continuous part of the text. Giving a negative step, i.e., -1 will return the text in reverse.

The `input()` function takes a string as argument and displays it to the user. Then it waits for the user to type something and press the return key. Once the user has entered, the `input()` function will then return that text.

We take that text and reverse it. If the original text and reversed text are equal, then the text is a palindrome (<http://en.wiktionary.org/wiki/palindrome>).

Homework exercise:

Checking whether a text is a palindrome should also ignore punctuation, spaces and case. For example, "Rise to vote, sir." is also a palindrome but our current program doesn't say it is. Can you improve the above program to recognize this palindrome?

Files

You can open and use files for reading or writing by creating an object of the `file` class and using its `read`, `readline` or `write` methods appropriately to read from or write to the file. The ability to read or write to the file depends on the mode you have specified for the file opening. Then finally, when you are finished with the file, you call the `close` method to tell Python that we are done using the file.

Example:

```
#!/usr/bin/python
# Filename: using_file.py

poem = '''\
Programming is fun
When the work is done
if you wanna make your work also fun:
    use Python!
'''

f = open('poem.txt', 'w') # open for 'w'riting
f.write(poem) # write text to file
f.close() # close the file

f = open('poem.txt') # if no mode is specified, 'r'ead mode is assumed
by default
while True:
    line = f.readline()
    if len(line) == 0: # Zero length indicates EOF
        break
    print(line, end='')
f.close() # close the file
```

Output:

```
$ python using_file.py
Programming is fun
```

```
When the work is done
if you wanna make your work also fun:
    use Python!
```

How It Works:

First, open a file by using the **built-in open function** and specifying the name of the file and the mode in which we want to open the file. **The mode can be a read mode ('r'), write mode ('w') or append mode ('a').** We can also be dealing with a text file ('t') or a binary file ('b'). There are actually many more modes available and `help(open)` will give you more details about them. **By default, `open()` considers the file to be a 't'ext file and opens it in 'r'ead mode.**

In our example, we first open the file in write text mode and use the write method of the file object to write to the file and then we finally close the file.

Next, we open the same file again for reading. We don't need to specify a mode because 'read text file' is the default mode. We read in each line of the file using the `readline` method in a loop. This method returns a complete line including the newline character at the end of the line. When an *empty* string is returned, it means that we have reached the end of the file and we 'break' out of the loop.

By default, the `print()` function prints the text as well as an automatic newline to the screen. We are suppressing the newline by specifying **`end=' '` because the line that is read from the file already ends with a newline character.** Then, we finally close the file.

Now, check the contents of the `poem.txt` file to confirm that the program has indeed written and read from that file.

Pickle

Python provides a standard module called `pickle` using which you can **store any Python object in a file and then get it back later.** This is called **storing the object persistently.**

Example:

```
#!/usr/bin/python
# Filename: pickling.py

import pickle

# the name of the file where we will store the object
shoplistfile = 'shoplist.data'
# the list of things to buy
shoplist = ['apple', 'mango', 'carrot']

# Write to the file
f = open(shoplistfile, 'wb')
pickle.dump(shoplist, f) # dump the object to a file
f.close()

del shoplist # destroy the shoplist variable

# Read back from the storage
```

```
f = open(shoplistfile, 'rb')
storedlist = pickle.load(f) # load the object from the file
print(storedlist)
```

Output:

```
$ python pickling.py
['apple', 'mango', 'carrot']
```

How It Works:

To store an object in a file, we have to first open the file in 'write 'binary mode' and then call the **dump function** of the pickle module. This process is called *pickling*.

Next, we retrieve the object using the **load function** of the pickle module which returns the object. This process is called *unpickling*.

Summary

We have discussed various types of input/output and also file handling and using the pickle module.

Next, we will explore the concept of exceptions.

Python en:Exceptions

Introduction

Exceptions occur when certain *exceptional* situations occur in your program. For example, what if you are going to read a file and the file does not exist? Or what if you accidentally deleted it when the program was running? Such situations are handled using **exceptions**.

Similarly, what if your program had some invalid statements? This is handled by Python which **raises** its hands and tells you there is an **error**.

Errors

Consider a simple print function call. What if we misspelt print as Print? Note the capitalization. In this case, Python *raises* a syntax error.

```
>>> Print('Hello World')
Traceback (most recent call last):
  File "<pyshell#0>", line 1, in <module>
    Print('Hello World')
NameError: name 'Print' is not defined
>>> print('Hello World')
Hello World
```

Observe that a `NameError` is raised and also the location where the error was detected is printed. This is what an *error handler* for this error does.

Exceptions

We will **try** to read input from the user. Press `ctrl-d` and see what happens.

```
>>> s = input('Enter something --> ')
Enter something -->
Traceback (most recent call last):
  File "<pyshell#2>", line 1, in <module>
    s = input('Enter something --> ')
EOFError: EOF when reading a line
```

Python raises an error called `EOFError` which basically means it found an *end of file* symbol (which is represented by `ctrl-d`) when it did not expect to see it.

Handling Exceptions

We can handle exceptions using the `try..except` statement. We basically put our usual statements within the `try`-block and put all our error handlers in the `except`-block.

```
#!/usr/bin/python
# Filename: try_except.py

try:
    text = input('Enter something --> ')
except EOFError:
    print('Why did you do an EOF on me?')
except KeyboardInterrupt:
    print('You cancelled the operation.')
else:
    print('You entered {}'.format(text))
```

Output:

```
$ python try_except.py
Enter something -->      # Press ctrl-d
Why did you do an EOF on me?

$ python try_except.py
Enter something -->      # Press ctrl-c
You cancelled the operation.

$ python try_except.py
Enter something --> no exceptions
You entered no exceptions
```

How It Works:

We put all the statements that might raise exceptions/errors inside the `try` block and then put handlers for the appropriate errors/exceptions in the `except` clause/block. The `except`

clause can handle a single specified error or exception, or a parenthesized list of errors/exceptions. If no names of errors or exceptions are supplied, it will handle *all* errors and exceptions.

Note that there has to be at least one `except` clause associated with every `try` clause. Otherwise, what's the point of having a `try` block?

If any error or exception is not handled, then the default Python handler is called which just stops the execution of the program and prints an error message. We have already seen this in action above.

You can also have an `else` clause associated with a `try...except` block. The `else` clause is executed if no exception occurs.

In the next example, we will also see how to get the exception object so that we can retrieve additional information.

Raising Exceptions

You can *raise* exceptions using the `raise` statement by providing the name of the error/exception and the exception object that is to be *thrown*.

The error or exception that you can arise should be class which directly or indirectly must be a derived class of the `Exception` class.

```
#!/usr/bin/python
# Filename: raising.py

class ShortInputException(Exception):
    '''A user-defined exception class.'''
    def __init__(self, length, atleast):
        Exception.__init__(self)
        self.length = length
        self.atleast = atleast

try:
    text = input('Enter something --> ')
    if len(text) < 3:
        raise ShortInputException(len(text), 3)
    # Other work can continue as usual here
except EOFError:
    print('Why did you do an EOF on me?')
except ShortInputException as ex:
    print('ShortInputException: The input was {0} long, expected at
least {1}'.format(ex.length, ex.atleast))
else:
    print('No exception was raised.')
```

Output:

```
$ python raising.py
Enter something --> a
```

```
ShortInputException: The input was 1 long, expected at least 3
```

```
$ python raising.py
Enter something --> abc
No exception was raised.
```

How It Works:

Here, we are creating our own exception type. This new exception type is called `ShortInputException`. It has two fields - `length` which is the length of the given input, and `atleast` which is the minimum length that the program was expecting.

In the `except` clause, we mention the class of error which will be stored as the variable name to hold the corresponding error/exception object. This is analogous to parameters and arguments in a function call. Within this particular `except` clause, we use the `length` and `atleast` fields of the exception object to print an appropriate message to the user.

Try ..Finally

Suppose you are reading a file in your program. How do you ensure that the file object is closed properly whether or not an exception was raised? This can be done using the `finally` block. Note that you can use an `except` clause along with a `finally` block for the same corresponding try block. You will have to embed one within another if you want to use both.

```
#!/usr/bin/python
# Filename: finally.py

import time

try:
    f = open('poem.txt')
    while True: # our usual file-reading idiom
        line = f.readline()
        if len(line) == 0:
            break
        print(line, end='')
        time.sleep(2) # To make sure it runs for a while
except KeyboardInterrupt:
    print('!! You cancelled the reading from the file.')
finally:
    f.close()
    print('(Cleaning up: Closed the file)')
```

Output:

```
$ python finally.py
Programming is fun
When the work is done
if you wanna make your work also fun:
!! You cancelled the reading from the file.
```

(Cleaning up: Closed the file)

How It Works:

We do the usual file-reading stuff, but we have arbitrarily introduced sleeping for 2 seconds after printing each line using the `time.sleep` function so that the program runs slowly (Python is very fast by nature). When the program is still running, press `ctrl-c` to interrupt/cancel the program.

Observe that the `KeyboardInterrupt` exception is thrown and the program quits. However, before the program exits, the `finally` clause is executed and the file object is always closed.

The with statement

Acquiring a resource in the `try` block and subsequently releasing the resource in the `finally` block is a common pattern. Hence, there is also a `with` statement that enables this to be done in a clean manner:

```
#!/usr/bin/python
# Filename: using_with.py

with open("poem.txt") as f:
    for line in f:
        print(line, end='')
```

How It Works:

The output should be same as the previous example. The difference here is that we are using the `open` function with the `with` statement - we leave the closing of the file to be done automatically by `with open`.

What happens behind the scenes is that there is a protocol used by the `with` statement. It fetches the object returned by the `open` statement, let's call it "thefile" in this case.

It always calls the thefile.`__enter__` function before starting the block of code under it and always calls thefile.`__exit__` after finishing the block of code.

So the code that we would have written in a `finally` block is should be taken care of automatically by the `__exit__` method. This is what helps us to avoid having to use explicit `try..finally` statements repeatedly.

More discussion on this topic is beyond scope of this book, so please refer PEP 343 (<http://www.python.org/dev/peps/pep-0343/>) for comprehensive explanation.

Summary

We have discussed the usage of the `try..except` and `try..finally` statements. We have seen how to create our own exception types and how to raise exceptions as well.

Next, we will explore the Python Standard Library.

Python en:Standard Library

Introduction

The Python Standard Library contains a huge number of useful modules and is part of every standard Python installation. It is important to become familiar with the Python Standard Library since many problems can be solved quickly if you are familiar with the range of things that these libraries can do.

We will explore some of the commonly used modules in this library. You can find complete details for all of the modules in the Python Standard Library in the 'Library Reference' section (<http://docs.python.org/dev/3.0/library/>) of the documentation that comes with your Python installation.

Let us explore a few useful modules.

Note

If you find the topics in this chapter too advanced, you may skip this chapter. However, I highly recommend coming back to this chapter when you are more comfortable with programming using Python.

sys module

The `sys` module contains system-specific functionality. We have already seen that the `sys.argv` list contains the command-line arguments.

Suppose we want to check the version of the Python command being used so that, say, we want to ensure that we are using at least version 3. The `sys` module gives us such functionality.

```
>>> import sys
>>> sys.version_info
(3, 0, 0, 'beta', 2)
>>> sys.version_info[0] >= 3
True
```

How It Works:

The `sys` module has a `version_info` tuple that gives us the version information. The first entry is the major version. We can check this to, for example, ensure the program runs only under Python 3.0:

```
#!/usr/bin/python
# Filename: versioncheck.py
import sys, warnings
if sys.version_info[0] < 3:
    warnings.warn("Need Python 3.0 for this program to run",
                  RuntimeError)
else:
    print('Proceed as normal')
```

Output:

```
$ python2.5 versioncheck.py
versioncheck.py:6: RuntimeWarning: Need Python 3.0 for this program
to run
    RuntimeWarning)

$ python3 versioncheck.py
Proceed as normal
```

How It Works:

We use another module from the standard library called `warnings` that is used to display warnings to the end-user. If the Python version number is not at least 3, we display a corresponding warning.

logging module

What if you wanted to have some debugging messages or important messages to be stored somewhere so that you can check whether your program has been running as you would expect it? How do you "store somewhere" these messages? This can be achieved using the logging module.

```
#!/usr/bin/python
# Filename: use_logging.py
import os, platform, logging

if platform.platform().startswith('Windows'):
    logging_file = os.path.join(os.getenv('HOMEDRIVE'),
os.getenv('HOMEPATH'), 'test.log')
else:
    logging_file = os.path.join(os.getenv('HOME'), 'test.log')

logging.basicConfig(
    level=logging.DEBUG,
    format='%(asctime)s : %(levelname)s : %(message)s',
    filename = logging_file,
    filemode = 'w',
)

logging.debug("Start of the program")
logging.info("Doing something")
logging.warning("Dying now")
```

Output:

```
$python use_logging.py
Logging to C:\Users\swaroop\test.log
```

If we check the contents of `test.log`, it will look something like this:

```
2008-09-03 13:18:16,233 : DEBUG : Start of the program
2008-09-03 13:18:16,233 : INFO : Doing something
2008-09-03 13:18:16,233 : WARNING : Dying now
```

How It Works:

We use three modules from the standard library - the `os` module for interacting with the operating system, the `platform` module for information about the platform i.e. the operating system and the `logging` module to *log* information.

First, we check which operating system we are using by checking the string returned by `platform.platform()` (for more information, see `import platform; help(platform)`). If it is Windows, we figure out the home drive, the home folder and the filename where we want to store the information. Putting these three parts together, we get the full location of the file. For other platforms, we need to know just the home folder of the user and we get the full location of the file.

We use the `os.path.join()` function to put these three parts of the location together. The reason to use a special function rather than just adding the strings together is because this function will ensure the full location matches the format expected by the operating system.

We configure the `logging` module to write all the messages in a particular format to the file we have specified.

Finally, we can put messages that are either meant for debugging, information, warning or even critical messages. Once the program has run, we can check this file and we will know what happened in the program, even though no information was displayed to the user running the program.

urllib and json modules

How much fun would it be if we could write our own program that will get search results from the web? Let us explore that now.

This can be achieved using a few modules. First is the `urllib` module that we can use to fetch any webpage from the internet. We will make use of Yahoo! Search to get the search results and luckily they can give us the results in a format called JSON which is easy for us to parse because of the built-in `json` module in the standard library.

TODO

This program doesn't work yet which seems to be a bug in Python 3.0 beta 2 (<http://bugs.python.org/issue3763>).

```
#!/usr/bin/python
# Filename: yahoo_search.py

import sys
if sys.version_info[0] != 3:
    sys.exit('This program needs Python 3.0')

import json
import urllib, urllib.parse, urllib.request, urllib.response

# Get your own APP ID at http://developer.yahoo.com/wsregapp/
YAHOO_APP_ID =
'j122psvV34HELWhdfUJbFDQzLJ2B57KFS_qs4I8D0Wz5U5_yCI1Awv8.lBSfPhwr'
SEARCH_BASE =
'http://search.yahooapis.com/WebSearchService/V1/webSearch'
```

```

class YahooSearchError(Exception):
    pass

# Taken from http://developer.yahoo.com/python/python-json.html
def search(query, results=20, start=1, **kwargs):
    kwargs.update({
        'appid': YAHOO_APP_ID,
        'query': query,
        'results': results,
        'start': start,
        'output': 'json'
    })
    url = SEARCH_BASE + '?' + urllib.parse.urlencode(kwargs)
    result = json.load(urllib.request.urlopen(url))
    if 'Error' in result:
        raise YahooSearchError(result['Error'])
    return result['ResultSet']

query = input('What do you want to search for? ')
for result in search(query)['ResultSet']:
    print("{0} : {1}".format(result['Title'], result['Url']))

```

Output:

TODO

How It Works:

We can get the search results from a particular website by giving the text we are searching for in a particular format. We have to specify many options which we combine using `key1=value1&key2=value2` format which is handled by the `urllib.parse.urlencode()` function.

So for example, open this link in your web browser (http://search.yahooapis.com/WebSearchService/V1/webSearch?query=byte+of+python&appid=jl22psvV34HELWhdfUJbfDQzlj2B57KFS_qs4l8D0Wz5U5_yCI1Awv8.IBSfPhwr&results=20&start=1&output=json) and you will see 20 results, starting from the first result, for the words "byte of python", and we are asking for the output in JSON format.

We make a connection to this URL using the `urllib.request.urlopen()` function and pass that file handle to `json.load()` which will read the content and simultaneously convert it to a Python object. We then loop through these results and display it to the end-user.

Module of the Week Series

There is much more to be explored in the standard library such as debugging (<http://docs.python.org/dev/library/pdb.html>), handling command line options (<http://docs.python.org/dev/3.0/library/getopt.html>), regular expressions (http://www.diveintopython.org/regular_expressions/index.html) and so on.

The best way to further explore the standard library is to read Doug Hellmann's excellent Python Module of the Week (<http://www.doughellmann.com/projects/PyMOTW/>) series.

Summary

We have explored some of the functionality of many modules in the Python Standard Library. It is highly recommended to browse through the Python Standard Library documentation (<http://docs.python.org/dev/3.0/library/>) to get an idea of all the modules that are available.

Next, we will cover various aspects of Python that will make our tour of Python more *complete*.

Python en:More

Introduction

So far we have covered majority of the various aspects of Python that you will use. In this chapter, we will cover some more aspects that will make our knowledge of Python more well-rounded.

Passing tuples around

Ever wished you could **return two different values from a function**? You can. All you have to do is use a tuple.

```
>>> def get_error_details():
...     return (2, 'second error details')
...
>>> errnum, errstr = get_error_details()
>>> errnum
2
>>> errstr
'second error details'
```

Notice that the usage of `a, b = <some expression>` interprets the result of the expression as a tuple with two values.

If you want to interpret the results as `(a, <everything else>)`, then you just need to star it just like you would in function parameters:

```
>>> a, *b = [1, 2, 3, 4]
>>> a
1
>>> b
[2, 3, 4]
```

This also means the fastest way to swap two variables in Python is:

```
>>> a = 5; b = 8
>>> a, b = b, a
>>> a, b
(8, 5)
```

Special Methods

There are certain methods such as the `__init__` and `__del__` methods which **have special significance in classes.**

Special methods are used to mimic certain behaviors of built-in types. For example, if you want to use the `x[key]` indexing operation for your class (just like you use it for lists and tuples), then all you have to do is implement the `__getitem__()` method and your job is done. If you think about it, this is what Python does for the `list` class itself!

Some useful special methods are listed in the following table. If you want to know about all the **special methods**, see the manual (<http://docs.python.org/dev/3.0/reference/datamodel.html#special-method-names>).

Name	Explanation
<code>__init__(self, ...)</code>	This method is called just before the newly created object is returned for usage.
<code>__del__(self)</code>	Called just before the object is destroyed
<code>__str__(self)</code>	Called when we use the <code>print</code> function or when <code>str()</code> is used.
<code>__lt__(self, other)</code>	Called when the <i>less than</i> operator (<code><</code>) is used. Similarly, there are special methods for all the operators (<code>+</code> , <code>></code> , etc.)
<code>__getitem__(self, key)</code>	Called when <code>x[key]</code> indexing operation is used.
<code>__len__(self)</code>	Called when the built-in <code>len()</code> function is used for the sequence object.

Single Statement Blocks

We have seen that each block of statements is set apart from the rest by its own indentation level. Well, there is one caveat. If your block of statements contains only one single statement, then you can specify it on the same line of, say, a conditional statement or looping statement. The following example should make this clear:

```
>>> flag = True
>>> if flag: print 'Yes'
...
Yes
```

Notice that the single statement is used in-place and not as a separate block. Although, you can use this for making your program *smaller*, I strongly recommend avoiding this short-cut method, except for error checking, mainly because it will be much easier to add an extra

statement if you are using proper indentation.

Lambda Forms

A lambda statement is used to create new function objects and then return them at runtime.

```
#!/usr/bin/python
# Filename: lambda.py

def make_repeater(n):
    return lambda s: s * n

twice = make_repeater(2)

print(twice('word'))
print(twice(5))
```

Output:

```
$ python lambda.py
wordword
10
```

How It Works:

Here, we use a function `make_repeater` to create new function objects at runtime and return it. A lambda statement is used to create the function object. Essentially, the lambda takes a parameter followed by a single expression only which becomes the body of the function and the value of this expression is returned by the new function. Note that even a print statement cannot be used inside a lambda form, only expressions.

TODO

Can we do a `list.sort()` by providing a compare function created using lambda?

```
points = [ { 'x' : 2, 'y' : 3 }, { 'x' : 4, 'y' : 1 } ]
# points.sort(lambda a, b : cmp(a['x'], b['x']))
```

List Comprehension

List comprehensions are used to derive a new list from an existing list. Suppose you have a list of numbers and you want to get a corresponding list with all the numbers multiplied by 2 only when the number itself is greater than 2. List comprehensions are ideal for such situations.

```
#!/usr/bin/python
# Filename: list_comprehension.py

listone = [2, 3, 4]
listtwo = [2*i for i in listone if i > 2]
print(listtwo)
```

Output:

```
$ python list_comprehension.py  
[6, 8]
```

How It Works:

Here, we derive a new list by specifying the manipulation to be done ($2*i$) when some condition is satisfied ($\text{if } i > 2$). Note that the original list remains unmodified.

The advantage of using list comprehensions is that it reduces the amount of boilerplate code required when we use loops to process each element of a list and store it in a new list.

Receiving Tuples and Lists in Functions

There is a special way of receiving parameters to a function as a tuple or a dictionary using the `*` or `**` prefix respectively. This is useful when taking variable number of arguments in the function.

```
>>> def powersum(power, *args):  
...     '''Return the sum of each argument raised to specified power.'''  
...     total = 0  
...     for i in args:  
...         total += pow(i, power)  
...     return total  
...  
>>> powersum(2, 3, 4)  
25  
  
>>> powersum(2, 10)  
100
```

Because we have a `*` prefix on the `args` variable, all extra arguments passed to the function are stored in `args` as a tuple. If a `**` prefix had been used instead, the extra parameters would be considered to be key/value pairs of a dictionary.

exec and eval

The `exec` function is used to execute Python statements which are stored in a string or file, as opposed to written in the program itself. For example, we can generate a string containing Python code at runtime and then execute these statements using the `exec` statement:

```
>>> exec('print("Hello World")')  
Hello World
```

Similarly, the `eval` function is used to evaluate valid Python expressions which are stored in a string. A simple example is shown below.

```
>>> eval('2*3')  
6
```

The assert statement

The `assert` statement is used to assert that something is true. For example, if you are very sure that you will have at least one element in a list you are using and want to check this, and raise an error if it is not true, then `assert` statement is ideal in this situation. When the `assert` statement fails, an `AssertionError` is raised.

```
>>> mylist = ['item']
>>> assert len(mylist) >= 1
>>> mylist.pop()
'item'
>>> mylist
[]
>>> assert len(mylist) >= 1
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
AssertionError
```

The `assert` statement should be used judiciously. Most of the time, it is better to catch exceptions, either handle the problem or display an error message to the user and then quit.

The repr function

The `repr` function is used to obtain a canonical string representation of the object. The interesting part is that you will have `eval(repr(object)) == object` most of the time.

```
>>> i = []
>>> i.append('item')
>>> repr(i)
"['item']"
>>> eval(repr(i))
['item']
>>> eval(repr(i)) == i
True
```

Basically, the `repr` function is used to obtain a printable representation of the object. You can control what your classes return for the `repr` function by defining the `__repr__` method in your class.

Summary

We have covered some more features of Python in this chapter and yet we haven't covered all the features of Python. However, at this stage, we have covered most of what you are ever going to use in practice. This is sufficient for you to get started with whatever programs you are going to create.

Next, we will discuss how to explore Python further.

Python en:What Next

If you have read this book thoroughly till now and practiced writing a lot of programs, then you must have become comfortable and familiar with Python. You have probably created some Python programs to try out stuff and to exercise your Python skills as well. If you have not done it already, you should. The question now is 'What Next?'.

I would suggest that you tackle this problem:

Create your own command-line *address-book* program using which you can browse, add, modify, delete or search for your contacts such as friends, family and colleagues and their information such as email address and/or phone number. Details must be stored for later retrieval.

This is fairly easy if you think about it in terms of all the various stuff that we have come across till now. If you still want directions on how to proceed, then here's a hint.

Hint (Don't read)

Create a class to represent the person's information. Use a dictionary to store person objects with their name as the key. Use the pickle module to store the objects persistently on your hard disk. Use the dictionary built-in methods to add, delete and modify the persons.

Once you are able to do this, you can claim to be a Python programmer. Now, immediately send me a mail (<http://www.swaroopch.com/contact/>) thanking me for this great book ;-). This step is optional but recommended. Also, please consider making a donation, contributing improvements or volunteering translations to support the continued development of this book.

If you found that program easy, here's another one:

Implement the replace command ([http:// unixhelp. ed. ac. uk/ CGI/ man-cgi?replace](http://unixhelp.ed.ac.uk/CGI/man-cgi?replace)). This command will replace one string with another in the list of files provided.

The replace command can be as simple or as sophisticated as you wish, from simple string substitution to looking for patterns (regular expressions).

After that, here are some ways to continue your journey with Python:

Example Code

The best way to learn a programming language is to write a lot of code and read a lot of code:

- The PLEAC project (http://pleac.sourceforge.net/pleac_python/index.html)
- Rosetta code repository (<http://www.rosettacode.org/wiki/Category:Python>)
- Python examples at java2s (<http://www.java2s.com/Code/Python/CatalogPython.htm>)
- Python Cookbook (<http://code.activestate.com/recipes/langs/python/>) is an extremely valuable collection of recipes or tips on how to solve certain kinds of problems using Python. This is a must-read for every Python user.

Questions and Answers

- Official Python Dos and Don'ts (<http://docs.python.org/dev/howto/doanddont.html>)
- Official Python FAQ (<http://www.python.org/doc/faq/general/>)
- Norvig's list of Infrequently Asked Questions (<http://norvig.com/python-iaq.html>)
- Python Interview Q & A (<http://dev.fyicenter.com/Interview-Questions/Python/index.html>)
- StackOverflow questions tagged with python (<http://beta.stackoverflow.com/questions/tagged/python>)

Tips and Tricks

- Python Tips & Tricks (<http://www.siafoo.net/article/52>)
- Advanced Software Carpentry using Python (<http://ivory.idyll.org/articles/advanced-swc/>)
- Charming Python (http://gnosis.cx/publish/tech_index_cp.html) is an excellent series of Python-related articles by David Mertz.

Books, Papers, Tutorials, Videos

The logical next step after this book is to read Mark Pilgrim's awesome Dive Into Python (<http://www.diveintopython.org>) book which you can read fully online as well. The Dive Into Python book explores topics such as regular expressions, XML processing, web services, unit testing, etc. in detail.

Other useful resources are:

- ShowMeDo videos for Python (<http://showmedo.com/videos/python>)
 - GoogleTechTalks videos on Python (http://youtube.com/results?search_query=googletechtalks+python)
 - Awaretek's comprehensive list of Python tutorials (<http://www.awaretek.com/tutorials.html>)
 - The Effbot's Python Zone (<http://effbot.org/zone/>)
 - Links at the end of every Python-URL! email (<http://groups.google.com/group/comp.lang.python.announce/t/37de95ef0326293d>)
 - Python Papers (<http://pythonpapers.org>)
-

Discussion

If you are stuck with a Python problem, and don't know whom to ask, then the `comp.lang.python` discussion group (<http://groups.google.com/group/comp.lang.python/topics>) is the best place to ask your question.

Make sure you do your homework and have tried solving the problem yourself first.

News

If you want to learn what is the latest in the world of Python, then follow the Official Python Planet (<http://planet.python.org>) and/or the Unofficial Python Planet (<http://www.planetpython.org>).

Installing libraries

There are a huge number of open source libraries at the Python Package Index (<http://pypi.python.org/pypi>) which you can use in your own programs.

To install and use these libraries, you can use Philip J. Eby's excellent EasyInstall tool (<http://peak.telecommunity.com/DevCenter/EasyInstall#using-easy-install>).

Graphical Software

Suppose you want to create your own graphical programs using Python. This can be done using a GUI (Graphical User Interface) library with their Python bindings. Bindings are what allow you to write programs in Python and use the libraries which are themselves written in C or C++ or other languages.

There are lots of choices for GUI using Python:

PyQt

This is the Python binding for the Qt toolkit which is the foundation upon which the KDE is built. Qt is extremely easy to use and very powerful especially due to the Qt Designer and the amazing Qt documentation. PyQt is free if you want to create open source (GPL'ed) software and you need to buy it if you want to create proprietary closed source software. Starting with Qt 4.5 you can use it to create non-GPL software as well. To get started, read the PyQt tutorial (<http://zetcode.com/tutorials/pyqt4/>) or the PyQt book (<http://www.qtrac.eu/pyqtbook.html>).

PyGTK

This is the Python binding for the GTK+ toolkit which is the foundation upon which GNOME is built. GTK+ has many quirks in usage but once you become comfortable, you can create GUI apps fast. The Glade graphical interface designer is indispensable. The documentation is yet to improve. GTK+ works well on Linux but its port to Windows is incomplete. You can create both free as well as proprietary software using GTK+. To get started, read the PyGTK tutorial (<http://www.pygtk.org/tutorial.html>).

wxPython

This is the Python bindings for the wxWidgets toolkit. wxPython has a learning curve associated with it. However, it is very portable and runs on Linux, Windows, Mac and even embedded platforms. There are many IDEs available for wxPython which include GUI designers as well such as SPE (Stani's Python Editor) (<http://spe.pycs.net/>) and

the wxGlade (<http://wxglade.sourceforge.net/>) GUI builder. You can create free as well as proprietary software using wxPython. To get started, read the wxPython tutorial (<http://zetcode.com/wxpython/>).

TkInter

This is one of the oldest GUI toolkits in existence. If you have used IDLE, you have seen a TkInter program at work. It doesn't have one of the best look & feel because it has an old-school look to it. TkInter is portable and works on both Linux/Unix as well as Windows. Importantly, TkInter is part of the standard Python distribution. To get started, read the Tkinter tutorial (<http://www.pythonware.com/library/tkinter/introduction/>).

For more choices, see the GuiProgramming wiki page at the official python website (<http://www.python.org/cgi-bin/moinmoin/GuiProgramming>).

Summary of GUI Tools

Unfortunately, there is no one standard GUI tool for Python. I suggest that you choose one of the above tools depending on your situation. The first factor is whether you are willing to pay to use any of the GUI tools. The second factor is whether you want the program to run only on Windows or on Mac and Linux or all of them. The third factor, if Linux is a chosen platform, is whether you are a KDE or GNOME user on Linux.

For a more detailed and comprehensive analysis, see Page 26 of the The Python Papers, Volume 3, Issue 1 (<http://archive.pythonpapers.org/ThePythonPapersVolume3Issue1.pdf>).

Various Implementations

There are usually two parts a programming language - the language and the software. A language is *how* you write something. The software is *what* actually runs our programs.

We have been using the *CPython* software to run our programs. It is referred to as CPython because it is written in the C language and is the *Classical Python interpreter*.

There are also other software that can run your Python programs:

Jython (<http://www.jython.org>)

A Python implementation that runs on the Java platform. This means you can use Java libraries and classes from within Python language and vice-versa.

IronPython (<http://www.codeplex.com/Wiki/View.aspx?ProjectName=IronPython>)

A Python implementation that runs on the .NET platform. This means you can use .NET libraries and classes from within Python language and vice-versa.

PyPy (<http://codespeak.net/pypy/dist/pypy/doc/home.html>)

A Python implementation written in Python! This is a research project to make it fast and easy to improve the interpreter since the interpreter itself is written in a dynamic language (as opposed to static languages such as C, Java or C# in the above three implementations)

Stackless Python (<http://www.stackless.com>)

A Python implementation that is specialized for thread-based performance.

There are also others such as CLPython (<http://common-lisp.net/project/clpython/>) - a Python implementation written in Common Lisp and IronMonkey (<http://wiki.mozilla.org/Tamarin:IronMonkey>) which is a port of IronPython to work on top of a JavaScript interpreter which could mean that you can use Python (instead of JavaScript) to write your web-browser ("Ajax") programs.

Each of these implementations have their specialized areas where they are useful.

Summary

We have now come to the end of this book but, as they say, this is the *the beginning of the end*!. You are now an avid Python user and you are no doubt ready to solve many problems using Python. You can start automating your computer to do all kinds of previously unimaginable things or write your own games and much much more. So, get started!

Python en:Appendix FLOSS

Free/Libre and Open Source Software (FLOSS)

FLOSS (<http://en.wikipedia.org/wiki/FLOSS>) is based on the concept of a community, which itself is based on the concept of sharing, and particularly the sharing of knowledge. FLOSS are free for usage, modification and redistribution.

If you have already read this book, then you are already familiar with FLOSS since you have been using **Python** all along and Python is an open source software!

Here are some examples of FLOSS to give an idea of the kind of things that community sharing and building can create:

- **Linux**. This is a FLOSS operating system that the whole world is slowly embracing! It was started by Linus Torvalds as a student. Now, it is giving competition to Microsoft Windows. [Linux Kernel (<http://www.kernel.org>)]
 - **Ubuntu**. This is a community-driven distribution, sponsored by Canonical and it is the most popular Linux distribution today. It allows you to install a plethora of FLOSS available and all this in an easy-to-use and easy-to-install manner. Best of all, you can just reboot your computer and run Linux off the CD! This allows you to completely try out the new OS before installing it on your computer. [Ubuntu Linux (<http://www.ubuntu.com>)]
 - **OpenOffice.org**. This is an excellent office suite with a writer, presentation, spreadsheet and drawing components among other things. It can even open and edit MS Word and MS PowerPoint files with ease. It runs on almost all platforms. [OpenOffice (<http://www.openoffice.org>)]
 - **Mozilla Firefox**. This is *the* next generation web browser which is giving great competition to Internet Explorer. It is blazingly fast and has gained critical acclaim for its sensible and impressive features. The extensions concept allows any kind of plugins to be used.
-

- Its companion product Thunderbird is an excellent email client that makes reading email a snap. [Mozilla Firefox (<http://www.mozilla.org/products/firefox>), Mozilla Thunderbird (<http://www.mozilla.org/products/thunderbird>)]
- **Mono**. This is an open source implementation of the Microsoft .NET platform. It allows .NET applications to be created and run on Linux, Windows, FreeBSD, Mac OS and many other platforms as well. [Mono (<http://www.mono-project.com>), ECMA (<http://www.ecma-international.org>), Microsoft .NET (<http://www.microsoft.com/net>)]
- **Apache web server**. This is the popular open source web server. In fact, it is *the* most popular web server on the planet! It runs nearly more than half of the websites out there. Yes, that's right - Apache handles more websites than all the competition (including Microsoft IIS) combined. [Apache (<http://httpd.apache.org>)]
- **MySQL**. This is an extremely popular open source database server. It is most famous for it's blazing speed. It is the M in the famous LAMP stack which runs most of the websites on the internet. [MySQL (<http://www.mysql.com>)]
- **VLC Player**. This is a video player that can play anything from DivX to MP3 to Ogg to VCDs and DVDs to ... who says open source ain't fun? ;-) [VLC media player (<http://www.videolan.org/vlc/>)]
- **GeexBox** is a Linux distribution that is designed to play movies as soon as you boot up from the CD! [GeexBox (<http://geebox.org/en/start.html>)]

This list is just intended to give you a brief idea - there are many more excellent FLOSS out there, such as the Perl language, PHP language, Drupal content management system for websites, PostgreSQL database server, TORCS racing game, KDevelop IDE, Xine - the movie player, VIM editor, Quanta+ editor, Banshee audio player, GIMP image editing program, ... This list could go on forever.

To get the latest buzz in the FLOSS world, check out the following websites:

- linux.com (<http://www.linux.com>)
- LinuxToday (<http://www.linuxtoday.com>)
- NewsForge (<http://www.newsforge.com>)
- DistroWatch (<http://www.distrowatch.com>)

Visit the following websites for more information on FLOSS:

- SourceForge (<http://www.sourceforge.net>)
- FreshMeat (<http://www.freshmeat.net>)

So, go ahead and explore the vast, free and open world of FLOSS!

Python en:Appendix About

Colophon

Almost all of the software that I have used in the creation of this book are *free and open source software*.

Birth of the Book

In the first draft of this book, I had used Red Hat 9.0 Linux as the foundation of my setup and in the sixth draft, I used Fedora Core 3 Linux as the basis of my setup.

Initially, I was using KWord to write the book (as explained in the History Lesson in the preface).

Teenage Years

Later, I switched to DocBook XML using Kate but I found it too tedious. So, I switched to OpenOffice which was just excellent with the level of control it provided for formatting as well as the PDF generation, but it produced very sloppy HTML from the document.

Finally, I discovered XEmacs and I rewrote the book from scratch in DocBook XML (again) after I decided that this format was the long term solution.

In the sixth draft, I decided to use Quanta+ to do all the editing. The standard XSL stylesheets that came with Fedora Core 3 Linux were being used. The standard default fonts are used as well. The standard fonts are used as well. However, I had written a CSS document to give color and style to the HTML pages. I had also written a crude lexical analyzer, in Python of course, which automatically provides syntax highlighting to all the program listings.

Now

For this seventh draft, I'm using MediaWiki (<http://www.mediawiki.org>) as the basis of my setup (<http://www.swaroopch.com/notes/>). Now I edit everything online and the readers can directly read/edit/discuss within the wiki website.

I still use Vim for editing thanks to the ViewSourceWith extension for Firefox (<https://addons.mozilla.org/en-US/firefox/addon/394>) that integrates with Vim.
